There is an obvious fundamental difference between these two strategies: *in situ* conservation involves the location, designation, management, and monitoring of target taxa where they are encountered, whereas *ex situ* conservation involves the location, sampling, transfer, and storage of target taxa from the target area. Because of this fundamental difference, there is little overlap between the two strategies. However, the two techniques should not be seen as alternative, they are complementary and should be applied in tandem to ensure maximum maintenance of diversity. The two basic conservation strategies may be further subdivided into the following specific techniques, which are discussed in sections *Ex Situ* Techniques and *In Situ* Techniques:

Ex Situ Seed/embryo storage *In vitro* storage Semen/ovule/pollen/deoxyribonucleic acid (DNA) storage Field gene bank/livestock parks Botanic/zoological garden, and *In Situ* Genetic reserve On-farm

Ex Situ Techniques

In *ex situ* conservation, genetic variation is maintained away from its original location and samples of a species, subspecies,

or variety are taken and conserved either as living collections of plants or animals in field gene banks, botanic or zoological gardens, and arboreta, or as samples of seed, semen, ovules, tubers, tissue explants, pollen, or DNA maintained under special artificial conditions.

Seed/Embryo Storage Conservation

Ex situ seed/embryo collection and storage is the most convenient and widely used method of genetic conservation (Figure 3). Seeds and embryos are the natural dispersal, storage, or generative organs for the majority of species. This technique involves collecting samples from individuals or populations and then transferring them to a gene bank for storage, usually at subzero temperatures. The procedure used for the bulk of orthodox-seeded plant species is to dry the seeds or embryos to a suitable moisture content (5–6%) before freezing at -20°C , but this method is only suitable for species that can be dried and stored at low temperature without losing viability. The advantages of this technique are that it is efficient and reproducible, and feasible for short-, medium-, and long-term secure storage. However, the disadvantages are that there are problems in storing recalcitrant-seeded plant species. The latter species cannot be dried and frozen in the way used for orthodox seeds, because they rarely produce seed or are normally clonally propagated.

Botanical/Zoological Garden Conservation

Historically, botanical or zoological gardens were often associated with physic or medicinal gardens or displays of single specimens of zoological curiosities, and as such they did not attempt to reflect the genetic diversity of the species. These gardens now hold living collections of species that were collected in a particular location and moved to the garden to be conserved. The advantage of this method is that gardens do not have the same constraints as many other conservation agencies; they have the freedom to focus on wild species that may otherwise not be given sufficient priority for conservation. Yet there are two disadvantages to this technique. The first is that the number of species that can be genetically conserved in a botanical or zoological garden will always be limited because of the available space. The majority of these gardens are located in urban areas in temperate countries, and

at their present sites most expansion would be prohibitively expensive. The majority of botanical and animal diversity is located in tropical climates, yet because most botanical and zoological gardens are in temperate countries, the collections must be kept in expensive greenhouses or other facilities, which also limits the space available. The second disadvantage is related to the first, namely very few individuals of each species can be held, and this severely restricts the range of genetic diversity found in the wild that is protected. However, if the target species is very near extinction and only one or two specimens remain extant, this objection of course does not hold.

In Vitro Conservation

In vitro conservation involves the maintenance of ex-plants in a sterile, pathogen-free environment, and it is widely used for vegetatively propagated and recalcitrant-seeded species. This method offers an alternative to field gene banks. It involves the establishment of tissue cultures of accessions on nutrient agar and their storage under controlled conditions of either slow or suspended growth. The main advantage is that it offers a solution to the long-term conservation problems of recalcitrant, sterile, or clonally propagated species. The main disadvantages are the risk of somaclonal variation, the need to develop individual maintenance protocols for the majority of species, and the relatively high-level technology and high cost required. The best answer for cheap, long-term *in vitro* conservation has been increasingly shown to be cryopreservation (Hoyt, 1988), that is, the storage of frozen tissue cultures at very low temperatures, for example, in liquid nitrogen at -196°C .

Field Gene Bank/Livestock Park Conservation

The conservation of germplasm in field gene banks or livestock parks involves the collecting of plant or animal specimens from one location and the transfer and conservation at a second site. It has traditionally been the method for recalcitrant- (whose seeds cannot be dried and frozen without loss of viability) or sterile-seeded plant species or for those species for which it is preferable to store clonal material. Field gene banks are commonly used for species such as cocoa, rubber, coconut, mango, coffee, banana, cassava, sweet potato, and yam. Livestock parks or rare breed centers, as distinct from zoos, emphasize captive breeding programs and therefore genetic conservation. The advantages of field gene banks and livestock parks are that the species are easily accessible for utilization and evaluation can be undertaken while the material is being conserved. The disadvantages are that the material is restricted in terms of genetic diversity, is susceptible to pests, disease, and vandalism, and may require large areas of land.

Pollen/Semen/Ovule/DNA Conservation

The storage of pollen grains is possible under appropriate conditions that allow their subsequent use for crossing with living plant material. It may also be possible in the future to regenerate haploid plants routinely from pollen cultures, but no generalized protocols have been developed yet. The development of artificial insemination techniques in recent years has made semen and ovule storage routine, especially for

Figure 3 Collecting seed from Tajikistan for *ex situ* conservation.

domesticated animals. The storage of DNA under prescribed conditions can easily and inexpensively be achieved given the appropriate level of technology, but the regeneration of entire organisms from DNA cannot be envisaged at present, although single or small numbers of genes could subsequently be utilized. The advantage of pollen storage is that it is low cost and simple, but the disadvantage is that only paternal material would be conserved, and with DNA storage there are problems with subsequent gene isolation, cloning, and transfer.

In Situ Techniques

In situ techniques involve the maintenance of genetic variation at the location where it is encountered, either in the wild or in traditional farming systems. The majority of existing nature reserves and natural parks were established to conserve megafauna or to protect esthetically beautiful landscapes, but even today few have less glamorous species conservation as their primary goal, let alone the genetic conservation of species (Hoyt, 1988).

Genetic Reserve Conservation

Conservation of wild species in a genetic reserve involves the location, designation, management, and monitoring of genetic diversity in a particular natural location (Figure 4). This technique is the most appropriate for the bulk of wild species, because it can, when the management regime is minimal, be relatively inexpensive. Whether dealing with plants or animals, the objective is to contain the minimum number of individuals that can maintain genetic diversity within the species. If too few individuals are protected, genetic diversity will decline over time, and if too many are protected, resources may be wasted in managing the large population. To guide such efforts, conservationists will need to estimate the effective population size (N_e), that is, the number of conserved individuals that would undergo the same amount of random genetic drift as the actual population. Genetic reserves are appropriate for animals as well as for orthodox and non-orthodox seeded plant species, because numerous taxa can be protected in a single reserve that allows the continued

Figure 4 Surveying plant populations for an *in situ* reserve in Turkey.

evolution of species. However, the disadvantages are that the conserved material is not immediately available for human exploitation and, if the management regime is minimal, little characterization or evaluation data may be available. In the latter case, the reserve manager may even be unaware of the complete specific composition of the reserve that he or she is managing.

On-Farm Conservation

Farmer-based conservation involves the maintenance of traditional crop or animal breeds or cultivation systems by farmers within traditional agricultural systems. On traditional farms, what are generally known as 'land-races' of plants are sown and harvested, and each season the farmers keep a proportion of harvested seed for re-sowing. Traditional breeds of domestic animal are maintained by interbreeding within and between local village stocks. Thus the land-race or breed is highly adapted to the local environment and is likely to contain locally adapted alleles that may prove useful for specific breeding programs. Home garden plant conservation is a closely related variant of on-farm conservation of land-races but on a smaller scale. It involves the cultivation of more species-diverse material in home, kitchen, backyard, or doorway gardens. These home gardens focus on medicinal, flavoring, and vegetable species (e.g., tomatoes, peppers, digitalis, mint, thyme, and parsley). The overall advantage of the on-farm technique is that it ensures the maintenance of highly adapted land-races and breeds and those wild species that traditional agriculture often depends on. However, these land-races or traditional breeds may yield less than their modern counterparts, and so traditional farmers may require some subsidy and possibly monitoring to ensure continued farming. It should be noted that contemporary economic forces tend to act against the continued farming of ancient land-races and breeds, which are currently suffering rapid genetic erosion; many face imminent extinction. A back-up system of *ex situ* conservation is therefore essential, as discussed in the section Sustainable and Integrated Biodiversity Conservation.

Community-Based Conservation

When applying all of the conservation techniques discussed here, professional conservationists have too often failed to appreciate the role that local communities have successfully played in conserving animal and plant diversity within their local environment in the past and how they might continue to contribute in the future. It is now generally accepted that the present-day wealth of domesticated and nondomesticated biodiversity would not exist were it not for the conscious effort of local communities over millennia to conserve biodiversity in all its forms. For example, indigenous farmers in the Andes maintain a gene pool of over 3000 varieties of potatoes representing eight cultivated species, and in Papua New Guinea approximately 5000 varieties of sweet potato are cultivated, with a single farmer growing up to 20 varieties in one garden (McNeely *et al.*, 1995). For wild species, Prance *et al.* (1995) showed that four groups of Amazonian Indians use up to 79% of the tree species in their home ranges, and Milliken *et al.* (1992) in a similar study found that 81% of tree and vine

species were utilized; this number rises to 86% when other categories of plants are added from literature sources.

So local communities have had and continue to have an essential role in biodiversity conservation. They not only continue to conserve by using traditional practices for their own future direct and indirect benefit, but also increasingly work in collaboration with professional conservationists to conserve broad-based biodiversity for the benefit of their host countries and humankind as a whole. Specifically, collaboration involving conservationists and local communities increases the overall efficiency of 'professional' conservation, because local communities have a broader local knowledge base concerning the animal and plant species found in their area. Local communities are therefore able to assist in the development of a more practical, focused, and hopefully efficient approach to locally targeted conservation. The employment of a collaborative approach also empowers local people and engenders increased pride in native biodiversity and its conservation. In this way, rather than deferring responsibility to outside science-based experts, they can retain environmental responsibility and take greater pride in maintaining their own environment.

Conservation Products

The products of conservation activities are primarily conserved germplasm (seed, embryos, semen, and ovules), live plants and animals, dried plants, cultures, and conservation data. *Ex situ* conserved orthodox seed or animal semen and ovules are commonly held in gene or semen banks at subzero temperatures and, for seed, low moisture content to prolong their life. Live plants or animals are conserved in genetic reserves, field gene banks, botanical or zoological gardens, or parks and research laboratories. Germplasm that is stored in a suspended form, such as tissue, pollen, or DNA, is kept as cultures in specialist laboratory facilities. Dried voucher plant specimens are held in herbaria and linked to specific samples of germplasm, and are as much as possible made representative of the conserved populations. Conserved material is ideally associated with a range of passport data, which detail the taxonomic, geographical, and ecological provenance of the

material. All passport data should be entered into a database and made available for the management of the material, the formulation of future conservation priorities and strategies, and any exploitation. The various conservation products, where they are stored, and where they should be duplicated are presented in Table 1.

Conserved Product Dissemination

The conservation products are either maintained in their original environment or deposited in a range of *ex situ* storage facilities. Whether the germplasm, voucher specimens, or passport data are conserved *in situ* or *ex situ*, to ensure their safety they should ideally be duplicated in more than one location. The distribution of duplicate sets of material avoids accidental loss of the material due to fire, economic or political difficulties, warfare, or other unforeseen circumstances. Duplication of the data is relatively easy from the conservation database, and copies should be held by the commissioning agency, relevant host country institutes, and other interested parties.

Biodiversity Utilization

As discussed earlier, if conservation is to be long term and sustainable there should be an intimate linkage between conservation and utilization. The products of conservation, whether they be 'living' or 'suspended,' should be made available for use by humankind for the various forms of utilization. Conservation can be seen as the safekeeping of preserved material, so that the material is available at a future date. In certain cases the material can be used directly, say in the selection of forage accessions or local domesticated animal breeds, where little breeding is undertaken. The conserved material may also be used in reintroduction programs where the traditional breed or land-race has been lost locally owing to civil unrest or the application of perverse government incentives that encourage the alteration of traditional practices.

More commonly, the first stage of utilization will involve the recording of genetically controlled characteristics (characterization) and the plant material may be grown out

Table 1 Conservation products and their storage and duplication sites

Conservation product	Storage site	Duplication site
Plant germplasm (seed, vegetative organs, etc.)	Gene bank	National, regional, and international gene banks, duplication with other conservation techniques
Animal germplasm (semen, ovules, eggs, embryos, etc.)	Gene bank	National, regional, and international gene banks, duplication with other conservation techniques
Live plants	Field gene bank, botanical garden, genetic reserve, on-farm	Duplication with other conservation techniques, for example, gene bank storage of seed
Live animals	Zoological garden, genetic reserve	Duplication with other conservation techniques, for example, storage of germplasm
Dried plants or preserved animals	Herbarium or museum	National, regional, and international herbaria or museums
Explants or plantlets	Tissue culture	Duplication with other conservation techniques, for example, gene bank storage of seed
DNA and pollen	Various cultures	Duplication with other conservation techniques, for example, gene bank storage of seed
Conservation data	Conservation database	Duplication with other national, regional, and international conservation agencies

under diverse environmental conditions to evaluate and screen for drought or salt tolerance, or be deliberately infected with diseases or pests to screen for particular biotic resistance (evaluation). As well as actual animal or plant characterization, increasingly geographic information systems are being used to help predict which accessions have desired traits, for example, climate change resilience in accession collected from arid areas. The biotechnologist will be screening for single genes, which when located may be transferred into a host organism to generate more rapid growth, for example. The biochemist (bioprospector) will be screening for particular chemical products that may be of use to the pharmaceutical industry. The products of utilization are therefore numerous, including new varieties, new crops, improved breeds, and pharmaceuticals as well as more nebulous but equally valuable products such as a beautiful or more diverse environment for human recreational activities.

Sustainable and Integrated Biodiversity Conservation

Having discussed in detail what constitutes biodiversity and how that biodiversity can be conserved, the point should be made that any biodiversity conservation program should be sustainable and integrated. Each conservation technique has its advantages and disadvantages. The two strategies of *ex situ* and *in situ* conservation should not be seen as alternatives or in opposition to one another, but rather as being complementary, as stated in Article 9 of the CBD (1992). One conservation strategy or technique can act as a backup to another, the degree of emphasis placed on each depending on the conservation aims, the type of species being conserved, the resources available, and whether the species has utilization potential. The efficacy of adopting an integrated approach to conservation, or as some have called it a 'holistic' approach (Withers, 1993), is now well established as the only sustainable option. Therefore, when formulating an overall conservation strategy for a species, conservationists should think in terms of applying a combination of the different techniques available, including both *in situ* as well as *ex situ* techniques, where the different methodologies complement each other. It may be helpful to think of the various techniques as pieces in a jig-saw puzzle that will complete the overall conservation strategy and thus ensure the maintenance of plant or animal genetic diversity.

The adoption of an integrated approach requires the conservationist to consider the characteristics and needs of the particular gene pool being conserved, and then to assess which of the strategies or combination of techniques offers the most appropriate option to maintain genetic diversity within that taxon. To formulate the conservation strategy, the conservationist may also need to address not only biological questions but also the practical and political ones: What are the species' storage characteristics? What do we know about its breeding success in captivity? Do we want to store the germ-plasm over the short, medium, or long term? How important is the species? Where is the species located and how accessible is it/does it need to be? Are there legal issues relating to access? How good is the infrastructure of the established reserves? What backup is necessary and desirable? How does the species

conservation strategy fit within the local community development program? Given answers to these questions, the appropriate combination of techniques to conserve the gene pool can be applied in a pragmatic and balanced manner. The integration of conservation and community development is an important point to stress. We cannot expect local communities to altruistically forgo development for the benefit of a more abstract greater good, and so the practical application of the conservation strategy may need to be a compromise between scientific protocols and meeting the needs and desires of local people. Therefore the actual combination of techniques will be formulated afresh for each species or group of species, demonstrating the flexibility of the integrated approach.

Sustainability in the sense of continuance is a fundamental concept for conservation. Whether seed, semen, or embryos are collected for *ex situ* conservation in a gene bank, animals are incorporated into a captive breeding program, or a habitat is designated as a reserve, each option has a financial cost and it would be a waste of limited conservation funds not to ensure that the conservation project is sustainable at least in the medium term. If the species or genetic material is lost from a reserve, the resources expended on establishing the reserve would have been wasted and the cost of rehabilitating populations using materials stored *ex situ* would have to be considered. The latter option is commonly expensive and may require extensive research to ensure that the reintroduced animals or plants do not likewise go extinct. Unfortunately, many conservation projects are funded on a short-term basis, so it is essential that an effective project exit strategy is developed so the conservation program itself is sustainable.

Not only is it necessary to integrate the different conservation strategies and techniques, and to involve the local community in a sustainable conservation project, but it is also important to integrate the different potential agencies involved. This is particularly true for large *in situ* reserve projects where the project may naturally span national borders and professional disciplines. In these cases, the project team must ensure that the local, provincial, national, regional, and international conservation agencies, as well as professionals from the different disciplines involved, such as environmentalists, foresters, agriculturalists, and politicians, work together to promote the success of the conservation project.

Landscape Corridors

Ellen I Damschen, University of Wisconsin-Madison, Madison, WI, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Connectivity Degree to which the landscape facilitates or impedes movement among habitat patches.

Corridor Linear strip of habitat connecting two otherwise isolated patches of suitable habitat.

Dispersal Movement of organisms, their propagules, or their genes away from their source.

Ecosystem services Resources and processes provided by natural systems that benefit humankind.

Functional traits Characteristics of species that define their ecological roles.

Local extinction When a species ceases to exist in an area that it historically occupied.

Matrix Landscape surrounding suitable habitat patches.

Movement When genes or organisms change location or position.

Patch Areas of suitable habitat that are different from the surrounding habitat (the matrix).

Rescue effect When the likelihood of local extinction in a habitat patch is reduced by emigrants from other habitat patches.

Introduction

Habitat fragmentation is one of the biggest drivers of species extinctions (Wilcove *et al.*, 1998). By severing movement pathways, the loss and fragmentation of habitat has been shown to decrease movement among habitat patches resulting in higher extinction rates (Pimm *et al.*, 1988), loss of gene flow (Lande and Shannon, 1996), decreased species diversity (Leach and Givnish, 1996), and diminished ecosystem services (Daily and Ellison, 2002; Kremen *et al.*, 2002). One proposed conservation solution for ameliorating these negative impacts is to use landscape corridors, or thin strips of habitat, to connect otherwise isolated habitat patches. By reducing local extinctions in habitat patches through increased colonizations (i.e., via “rescue effects” sensu; Brown and Kodric-Brown, 1977), corridors have been theorized to increase gene flow, population sizes, species persistence, and species diversity.

Landscape corridors are also referred to by other names, including “habitat corridors” and “wildlife corridors” (specifically referring to corridors for particular animals). Here, “corridor”, “landscape corridor”, and “habitat corridor” are used interchangeably to refer to linear habitat linkages that connect otherwise isolated patches of suitable habitat. Corridors have also been defined in both structural (i.e., the physical presence of a corridor in a landscape) and functional (i.e., serving to promote movement across a landscape) ways, which has created confusion when communicating about corridors (Hess and Fischer, 2001). Here the author discusses how the presence of structural corridors (i.e., linear strips of habitat) affects various ecological functions (e.g., movement, gene flow, population sizes, species diversity). In addition, “landscape connectivity” is a closely related concept in that it is the degree to which the landscape facilitates or impedes movement among resource patches (Taylor *et al.*, 1993; Dunning *et al.*, 1992). Corridors are, therefore, a narrower definition housed within landscape connectivity.

Historical Background

Landscape corridors conceptually emerged from applied island biogeography (Wilson and Willis, 1975) and metapopulation theory (Levins, 1969). This body of theory suggested that larger areas of habitat are better than smaller areas, that habitat patches closer together are better than those farther apart, and that otherwise isolated habitat patches connected with a corridor are better than those without such a connection (Figure 1). The intuitive appeal of these proposed designs led to landscape corridors becoming a common feature in the design and implementation of reserves. The Yellowstone to Yukon Conservation Initiative (Y2Y) and the Mesoamerican Biological Corridor from Mexico through Central America are two examples where corridors are being implemented at continental scales. Corridors are also frequently being implemented in regional (e.g., the Talamancan-Caribbean Biological Corridor in Costa Rica) and local landscapes (e.g., Metro Conservation Corridors in the Twin Cities, MN).

Empirical evidence documenting whether and how corridors function, however, has lagged behind implementation. Questions have risen about whether corridors are the most effective conservation strategy in comparison to, for example, preserving additional area alone. And, some have suggested caution about the potential for corridors to have detrimental impacts (e.g., increasing predation risk, spreading disease or fire; Simberloff *et al.*, 1992; Beier and Noss, 1998; Hess, 1994; Orrock and Damschen, 2005). Studies have begun to accumulate over the past decade, allowing for a more informed understanding of whether and how corridors function. Here I do not attempt to conduct an exhaustive literature review (but see Crooks and Sanjayan, 2006; Hilty *et al.*, 2006; Gilbert-Norton *et al.*, 2010; Rosenberg *et al.*, 1997 and the references therein) but instead rely on specific examples to demonstrate key points in the evolution of our understanding of corridor effects.

Figure 1 Some of the better and worse reserve designs proposed by Wilson and Willis (1975): (a) larger patches are better than smaller patches, (b) patches closer together are better than those farther apart, and (c) patches connected by corridors are better than isolated patches.

Separating Connectivity Effects from Confounding Factors

Corridor effects can arise from one of three mechanisms: (1) connectivity, whereby corridors increase movement between connected patches; (2) area, because corridors also increase the amount of suitable habitat any increase in movement, population sizes, or diversity could be due to the availability of additional habitat rather than because of a connection per se; and (3) patch shape, because corridors change the shape of a habitat patch by increasing the amount of edge habitat relative to core habitat, responses could be due to patch-shape effects rather than connectivity. Observational studies of existing landscapes are often unable to control for these three separate factors. However, some experiments have explicitly manipulated these factors so that the mechanisms underpinning corridor responses can be deciphered.

Measuring Corridor Responses

The effectiveness of corridors can be evaluated using a variety of metrics. The most commonly measured response is the movement of individuals among habitat patches. This can be done in a variety of ways, including creating mathematical or simulation models, marking and recapturing organisms, conducting real-time follows of organisms as they move, using dyes to trace movement patterns, or determining genetic similarities to infer movement over time. A less commonly measured response is the effect of corridors on population sizes. In large part, this is because tracking populations requires long-term demographic data, which are difficult to obtain at large spatial scales. Similarly, studies of community-level processes (e.g., predator–prey dynamics,

species diversity) are also less frequent because they can require the identification of large numbers of organisms often over multiple years. The latter two types of studies (population and community levels) are important to tackle because they are often the ultimate goal of corridor implementation: to prevent species declines and extinctions and to increase biodiversity.

Evidence from Models

Theoretical and simulation models exploring the impact of corridors and connectivity on ecological processes can illuminate new avenues for research, tackle empirically challenging questions, and provide predictive power.

One of the most informative uses of simulation models in corridor research has been to determine how species will respond to various habitat configurations in conjunction with actual conservation decisions. Paul Beier and colleagues have developed such models using geographic information systems (GIS) to illuminate pathways of least resistance or cost to organisms (e.g., Beier *et al.*, 2009; McRae *et al.*, 2008). These models have helped identify habitat connections and prioritize conservation efforts (Beier *et al.*, 2008). For example, the South Coast Missing Linkages project in Southern California utilized this approach for identifying key habitat corridors amid an urban matrix (Beier, 2006).

Simulation models have also been especially useful for evaluating the potential outcomes of negative corridor effects, which may pose special ethical challenges for testing in the field and for considering evolutionary effects that are unable to be tested over short time scales. For example, Hess (1994) determined how corridors might affect the spread of disease

and found that connecting otherwise isolated habitat patches could lead to faster rates of spread (Hess, 1994). By exploring these effects through a model, hypotheses could be initially tested and the study's findings could be used to appropriately guide tests in real landscapes (e.g., Johnson and Haddad, 2011). In another example, Earn *et al.* (2000) determined that landscape connectivity may lead to negative effects by promoting connectivity-mediated synchrony. For evolutionary effects, Orrock (2005) explored how corridors affect rates of adaptive evolution and determined that the effects can be positive or negative, depending on the frequency of disturbance. When disturbance is rare, corridors increase the fixation of beneficial alleles and the loss of harmful alleles (Orrock, 2005). However, when disturbance rates are high, the opposite occurs.

Empirical Evidence

Observational Studies

Observational field studies of corridor effects have provided insight into corridor function by incorporating realistic landscape features such as heterogeneous resources and large spatial scales. Although observational studies provide a very important endpoint on the continuum of understanding corridor effects, they are also limited because they can be confounded by features that co-occur in natural landscapes (e.g., connectivity, area, and patch-shape effects; *see* Separating Connectivity Effects from Confounding Factors) and may lack true replication. Here the author includes what others have referred to as "quasi-experiments" (Rosenberg *et al.*, 1997) or "natural experiments" (Gilbert-Norton *et al.*, 2010) as observational studies since they do not include randomized manipulations or true controls.

One of the earliest studies of corridor effects in real landscapes was reported by MacClintock *et al.* (1977), who demonstrated that bird species richness was higher in a single forest patch that was connected to other forested habitat by a corridor than in another unconnected forest patch. Notably, this early study was conducted at the community level, which remains a challenge for ecologists to study at landscape scales. However, this study contained a single replicate, so although the study's findings were intriguing they were not especially robust.

Several observational studies have made use of existing shelterbelts (wooded habitats planted to provide windbreaks within agricultural landscapes) that connect otherwise isolated woodlots within agricultural settings. Haas (1995) found that shelterbelts in south central North Dakota, USA, promoted the movement of Robins and Thrashers. Harvey (2000) found that shelterbelts in Monteverde, Costa Rica that were connected to forest habitat had higher forest tree-seedling densities and greater numbers of forest tree species. This was likely due to frugivorous birds moving more frequently through the connected shelterbelts because the density and diversity of bird-dispersed tree species were especially high. These studies suggested that corridors (i.e., shelterbelts) promoted movement of birds and bird-dispersed seeds, but because the size and spacing of shelterbelts was not controlled, these studies were unable to determine how corridors functioned.

A quasi-experimental study of corridor effects on diversity was conducted by Schmiegelow *et al.*, (1997) using habitat patches of different sizes that were either connected or unconnected to adjacent existing habitat. However, this study did not control for the area of the corridor. Surprisingly, they found weak effects of corridors and the highest diversity was found in the smallest patch size, which contradicted theoretical predictions. However, area and connectivity effects were confounded in this study because the corridors in their system were wider than the smallest habitat patches. In addition, patches were nonrandomly located so connected patches were always adjacent to riparian areas, resulting in location and connectivity being confounded. This study demonstrated the importance of controlling for the various mechanisms by which corridors can work and for the quality of the surrounding habitat matrix.

Machtans *et al.* (1996) also conducted a quasi-experiment before and after the harvesting of forests that were adjacent to riparian buffer strips. They measured the frequency of bird movements through these landscapes and found that buffer strips enhanced movement of juveniles by promoting connectivity and maintained the movement rates of adults. They also found that corridors were used less frequently when interpatch distances were small, suggesting that corridors may be more important at larger spatial scales where movement is disproportionately enhanced by the presence of corridor.

One of the most robust approaches that can be used in observational studies is to infer landscape connectivity from genetic similarity among individuals because it is a measure that integrates past organism movement across landscapes. For example, Hale *et al.* (2001) measured gene flow in British red squirrels in the UK. They found that recent plantings of conifer forests, which connected habitat fragments in the north of England with the south of Scotland, increased the amount of genetic mixing in squirrel populations. In another example, McRae and Beier (2007) determined genetic similarity for several types of organisms and then correlated this with modeled measures of landscape connectivity. They found an especially effective metric was the amount of landscape "resistance," analogous to electrical resistance, which was strongly correlated with the genetic similarity of the organisms studied. Such tight links between models and data hold promise for predicting the movement of organisms across large landscapes.

Experimental Studies

Experimental studies can overcome some of the inherent challenges of observational systems in that they can control for various factors (e.g., area, connectivity, patch shape) that would otherwise be confounded. They also can use higher levels of replication that can provide robust tests of corridor effects. Controlled and replicated experiments, however, are logistically difficult to conduct at large scales, so most experiments have been conducted using microcosms, mesocosms, or small field plots. Such studies lack the realism of actual landscapes where corridors are being implemented but allow for a more complete understanding of the mechanisms underlying corridor effects. In the following sections,

the author highlights some of the corridor experiments that have been conducted and synthesizes some of the key findings.

Microcosms and Mesocosms

Burkey (1997) provided one of the first experimental tests of corridor function. He used simple communities of bacteria and protozoa in vessels (pits in Plexiglas plates) that were connected with corridors created by removing part of the cylinder wall separating adjacent vessels. The experimental communities contained three trophic levels, and the time to extinction for the top predator was measured in habitats that were different sizes and with different levels of connectivity. Burkey found that fragmented vessels went extinct sooner than

unfragmented vessels of the same overall size. However, vessels connected by corridors went extinct significantly sooner than those that were isolated. This study suggested that corridors could have “negative” impacts on some species – in this case, on the top predator in the community – and suggested caution for establishing corridors in fragmented landscapes.

Holyoak (2000) also conducted studies of corridor effects within microcosms (Figure 2(a)). He determined how long predator and prey protists persisted in microcosms with different numbers of patches with and without corridors. Holyoak found that metapopulation persistence for the predator could be predicted by the number of patches and corridors, the maximum interpatch distance, and the proportion of patches that provided colonists. However, loops of

patches generated unexpected results that were not predicted by theory and suggested the need for combining models with experimentation to understand the mechanisms underlying connectivity effects.

A series of mesocosm studies by Andrew Gonzalez, Francis Gilbert, and colleagues have provided robust tests of corridor effects for microarthropod communities within small (~ 10 cm) patches of moss (Gilbert *et al.*, 1998; Gonzalez and Chaneton, 2002; Gonzalez *et al.*, 1998; Hoyle and Gilbert, 2004). Higher levels of microarthropod diversity and slower extinction rates (contrary to Burkey, 1997) were found in moss patches connected by a corridor (Gilbert *et al.*, 1998; Gonzalez and Chaneton, 2002; Gonzalez *et al.*, 1998). However, a study conducted in the same system several years later found that corridors did not slow the rate of extinction or increase species richness (Hoyle and Gilbert, 2004). The authors concluded that this was likely because of changes in weather and that corridors may be more important for mitigating extinctions during extreme rather than moderate weather conditions. This study revealed that time and environmental conditions might be an important determinant of corridor effectiveness. In new research, Andrew Gonzalez and colleagues are attempting to understand the interaction between connectivity and climate change (i.e., environmental conditions) using microarthropod community mesocosms within open-top warming chambers (Figure 2(b)).

Rantalainen *et al.* (2004a, b, 2005) conducted several mesocosm experiments using soil decomposer organisms as a model system. These studies found that corridors increased the species richness of soil fungi in the patches they connected. In addition, corridors sometimes increased the abundance of enchytraeid worms, the species richness of bacteria (dispersed by enchytraeid worms), and the number of microarthropod taxa. One important conclusion from these studies was that corridor effects can depend on particular species interactions and trophic levels.

Plot-based Experiments

One of the first studies to use large field plots to experimentally test for the effects of corridors was conducted by Aars and Ims (1999) who used 20-m $\times$ 37.5-m patches of dense meadow vegetation connected by 50-m long corridors within a habitat matrix that was herbicided and fenced (Figure 2(c)). This study measured the movement of individuals by tracking levels of genetic heterozygosity among vole demes. Voles within patches connected by a corridor exhibited enhanced interbreeding rates as compared to those within unconnected patches. This has been one of the only experimental studies to examine how corridors affect rates of gene flow and suggests that such connections do enhance the movement of genes. However, the study design did not control for area or patch shape effects, so the underlying mechanism by which corridors operated was not determined.

Coffman *et al.* (2001) conducted another plot-based experiment that tested the impact of corridors on meadow vole populations. Corridors promoted movement and increased survival but did not have any effect on population sizes or recruitment. Populations in better-connected plots, however, had more stable population sizes over time. This study is one of the few that has explicitly measured corridor effects on

population sizes and demography, but again the mechanisms responsible for the effects observed were not deciphered.

Another experimental study of corridors was conducted by Sharon Collinge, who used grassland patches within a matrix of mowed vegetation (Figure 2(d)) to test for corridor effects on arthropod communities (Collinge, 2000). She found weak effects of corridors on insect diversity and attributed these findings to inadequate contrast between the patch and matrix habitat. In addition, the dispersal ability of the insects within the study system may have been much greater relative to the size and isolation of the patches. Both findings suggested the importance of habitat contrast and the scale of the landscape relative to dispersal ability for determining corridor function.

Landscape Experiments

Experimental tests of corridors at landscape scales offer the promise of providing realistic predictions for real-world landscapes while controlling for factors that are often confounded at such large scales (e.g., area, patch shape, and connectivity). At Savannah River Site, SC, Nick Haddad and the Corridor Research Group created two such experiments to test for the effects of corridors, one of which controlled for area and patch shape. These have been the largest experimental tests of corridors.

In the first experiment, 1.64 ha patches were connected or unconnected by different length corridors (64, 128, 256, and 384 m long). The impacts were subsequently measured on the movement of butterflies, bees, birds, and small mammals (e.g., Haddad *et al.*, 2003; Haddad, 1999a, b; Haddad and Baum, 1999; Danielson and Hubbard, 2000). In general, all 10 of the study species exhibited positive corridor effects (i.e., the percentage increase in movement between connected relative to unconnected patches). Of the 10 species that were examined, five moved significantly more often between connected patches than those that were isolated. For the remaining five species, four appeared to be directed by corridors, but the results were inconclusive because of low sample size. One rodent species (*Sigmodon hispidus*) did not move preferentially between connected patches, likely because the scale of the study was too small for movement of this species across landscapes. In separate studies on the effects of corridor length, movement among patches connected by a corridor was negatively related to corridor length, but corridors increased overall interpatch movement when compared to movement through the surrounding matrix. This suggests that corridors promote movement, which may be especially important ecologically at large spatial scales where infrequent migrants have large impacts on population persistence.

The second experiment was designed to separate the mechanisms by which corridors work – through connectivity, area, or patch-shape effects – by controlling for each factor. Eight experimental landscapes were created, each with a central 100-m $\times$ 100-m open habitat patch (Figure 3). Four peripheral patches surrounded this center patch with three different patch types. *Connected* patches were 100-m $\times$ 100-m patches connected by a 150-m long corridor to the central patch. *Rectangular* patches were 100-m $\times$ 137.5-m patches that remained unconnected but controlled for habitat area by adding the area of the corridor to a 100-m $\times$ 100-m patch. *Winged* patches were 100-m $\times$ 100-m patches with two

Figure 3 The experimental design used to test the mechanisms by which corridors work at the Savannah River Site, SC, USA. A central 100-m $\times$ 100-m patch is surrounded by four peripheral patches that are either connected or unconnected by a corridor. Unconnected patches are of two types: *Rectangular* patches that control for the area of the corridor and *Winged* patches that control for patch shape. Photo credit: Ellen Damschen.

dead-end “wings” projecting from opposite sides of this patch that were each one-half the length of a corridor. These patches had the same area and amount of edge habitat as a connected patch but remained unconnected. By comparing responses in connected, rectangular, and winged patches, it has been possible to determine how corridors are functioning.

Studies from this experiment also found increased movement of birds, plants, and butterflies between patches connected by a corridor (e.g., Levey *et al.*, 2005; Tewksbury *et al.*, 2002; Haddad and Tewksbury, 2005) as well as increased densities for three butterfly species (Haddad and Baum, 1999) and increased gene flow for one butterfly species (*Junonia coenia*) (Wells *et al.*, 2009). In addition, small-scale movement behavior of animals was found to correspond with whether species will use corridors at larger scales (Levey *et al.*, 2005), which suggested that understanding local movement behavior of organisms may allow corridor effects to be predicted.

There was also evidence for negative corridor effects from studies conducted within this experiment. For example, some bird species had decreased survival in connected patches (Weldon, 2006; Weldon and Haddad, 2005). This response was due, however, to patch-shape effects (i.e., because linear landscape features such as corridors necessarily have higher edge-to-area ratios than larger contiguous habitat patches) rather than connectivity effects per se. The birds were preferentially nesting along habitat edges, where they had poor nest success and decreased survival in edgier connected patches. In another example, seeds were more likely to be predated by small mammals in connected patches (Orrock *et al.*, 2003; Orrock and Damschen, 2005). However, seeds consumed by invertebrates exhibited the opposite

response, resulting in no difference in total predation (by both types of predators) between connected and unconnected patches (Orrock *et al.*, 2003). This and a subsequent study (Orrock and Damschen, 2005) of two seed species that varied in size demonstrated that corridor effects may differentially affect plant species within the same community. In addition, these studies suggested that corridors may have both positive and negative effects on the same species at different life stages.

Despite these potentially negative impacts of corridors on individual species or life stages, the net effect of corridors on plant community diversity in this system has been positive. Plant species richness was higher in connected versus unconnected patches, and this difference increased over time (Damschen *et al.*, 2006). Various groups of species, however, likely respond uniquely to corridors. For plants, bird-dispersed species responded most strongly and quickly to the connections that corridors provide, whereas wind-dispersed species responded to both patch shape and connectivity effects (Damschen *et al.*, 2008). In another community-level study, there were fewer genera of arthropods and less species turnover in connected patches due to patch-shape effects, whereas evenness was lower in connected patches due to connectivity effects (Orrock *et al.*, 2011). Both of these community level studies of plants and insects suggest that subsets of species within a community respond uniquely to corridors. Understanding species functional traits may provide keys to predicting corridor use.

The Savannah River Site corridor experiments have shown that corridors increase movement for the vast majority of species that have been studied (13 out of 15 species; Haddad *et al.*, 2011). The few cases where corridors have resulted in

negative effects were related to the increased prevalence of edges in connected patches, suggesting that changes in patch shape are more likely responsible for negative impacts than connectivity effects per se (Haddad *et al.*, 2011). Additional studies also found that corridor effects can be predicted by understanding small-scale movements (Haddad, 1999b; Levey *et al.*, 2005) and life-history traits such as the dispersal mode of plants (Damschen *et al.*, 2008).

Conclusions and Future Directions

Synthesizing Current Evidence

Models and observational and experimental studies have demonstrated the utility of corridors in promoting the movement of organisms among the habitat patches they connect. In the majority of cases, corridors have resulted in positive effects for the organisms of interest, including plants, insects, and small mammals (Haddad *et al.*, 2003; Gilbert-Norton *et al.*, 2010). In a recent meta-analytic review of 78 experiments from 35 corridor studies, Gilbert-Norton *et al.* (2010) determined that corridors increased interpatch movement by ~50% when compared to unconnected patches. The cases where corridors have caused neutral or negative effects demonstrate the importance of understanding organism life histories, how the scale of organism movement relates to the landscape, and the underlying mechanisms responsible for corridor use (e.g., connectivity or patch shape effects).

In a small number of cases, corridors have resulted in negative impacts for the species of interest (e.g., Orrock and Damschen, 2005; Hess, 1994; Johnson and Haddad, 2011; Haddad *et al.*, 2011). For example, corridors increased disease transmission in the model by Hess (1994), which was corroborated by a later field study by Johnson and Haddad (2011). Importantly, however, the model was unable to decipher the mechanisms underlying the response to corridors, but the field test was able to do so by experimentally controlling for connectivity, area, and patch-shape effects. The field experiment determined that disease spread was driven by distance from habitat edges (i.e., patch-shape effects due to high edge-to-area ratios in connected patches) rather than connectivity effects per se. In fact, the majority of “negative” corridor effects have been driven by patch-shape and edge effects (Haddad *et al.*, 2011).

For some species, the presence of a corridor has not affected movement or been less effective in promoting movement than the nonhabitat matrix (Haddad *et al.*, 2003). Often, this has been due to the life history traits of the organism. For example, species that are habitat generalists may not respond because quality of the corridor habitat is not different from the surrounding matrix, and these organisms can move through both habitat types equally well (Haddad, 1999b). Or, if the species is migratory and the migratory pathways are in a particular direction, then corridors may not be used unless they are also in the same direction as the migration (Haddad, 1999b). Other reasons for such responses include if the suitability of habitat types is not understood or has been misclassified or if the scale

of the study is not appropriate for the study organism (Gilbert-Norton *et al.*, 2010; Haddad, 1999b). These responses demonstrate the importance of understanding the life history of the target species for which a corridor may be designed in relation to landscape features such as matrix quality (Prugh *et al.*, 2008).

Future Directions

The last decade has provided great insight into corridor function, but much yet remains to be understood. In particular, most studies have focused on organism movement alone, whereas the effects of corridors on population size, genetic diversity, and species diversity have received much less attention (Gilbert-Norton *et al.*, 2010). In addition, most studies have been conducted over relatively short time scales, preventing an understanding of long-term population and community dynamics. Future studies are needed to determine whether increased movement results in reduced population extinction rates and increased species diversity over the long term.

Other factors that need to be explored include the role of corridor quality and the habitat matrix in promoting or hindering movement (Prugh *et al.*, 2008). One study found that low-quality corridors promoted the movement of two butterfly species even though they did not establish resident populations and preferred core habitat (Haddad and Tewksbury, 2005). However, for other species that must move through corridors across multiple generations such as plants, habitat quality may be more important. A key conservation question is whether land acquired for corridors is of appropriate quality and contrast to the matrix to achieve management goals.

Corridor studies have also almost exclusively been conducted in terrestrial settings. There are only a handful of examples from marine and freshwater ecosystems. Darcy and Eggleston (2005) conducted a study to determine how seagrass corridors affected the movement of benthic organisms. They found that corridors facilitated the movement of slow-moving polychaete worms, but not for faster-moving species such as grass shrimp and bay scallops. For the faster-moving species, water currents seemed to affect dispersal more than the presence of a habitat corridor. These results from an aquatic system corroborate those from terrestrial settings and similarly suggest that understanding the life history of organisms and how their movement is affected by landscape features is critical for predicting corridor function. In particular, the scale of the corridor relative to the scale at which organisms make movement decisions is a key factor for determining if corridors will promote dispersal. Future studies of corridor effects across ecosystems may help elucidate generalities such as these.

A critical conservation question that has not been adequately addressed is how corridor width affects species. Early studies by La Polla and Barrett (1993) and Andreassen *et al.* (1996) tackled this question by monitoring the movement of voles in a plot-based experiments. La Polla and Barrett (1993) found that corridor presence was more important than width for the movement of male meadow voles within their home

range. Although Andreassen *et al.* (1996) found that a corridor of intermediate width (1 m) promoted movement of root voles better than narrower (0.4 m) or wider (3 m) corridors. In another study of corridor width and quality on Deermice, Ruefenacht and Knight (1995) found that corridor width had no effect but that tree densities were the major driver of movement. Since these studies, there have been no other experimental tests of how corridor width affects movement (let alone population sizes or community diversity) despite the fact that land managers continue to search for answers to this question.

A related question that needs addressing is how the relative scales of organism movement and landscapes might help predict corridor responses. Gilbert-Norton *et al.* (2010) found that corridors worked equally well for all taxa they examined except birds (which still had a positive effect size), which they hypothesized was due to the fact that experiments were more difficult to appropriately scale for birds since they can easily travel large distances over matrix habitat. Further work is needed to explore how scales of organism movement relate to scales of landscape heterogeneity.

Finally, corridors have often been implemented to minimize potential risks of climate change by facilitating the movement of species to newly created suitable habitat from locations where habitat has become unsuitable. However, there has been virtually no research dedicated to this topic. Andrew Gonzalez and colleagues are conducting a new study that addresses whether or not corridors facilitate species persistence in habitats with varying climate (Figure 2(b)). Their experimental moss arthropod mesocosm study system is particularly well suited for tackling this challenging question in that manipulating both connectivity and climate at landscape scales would not be possible. By using mesocosms that include connected and unconnected patches embedded within a series of warming open-top chambers (and controls), they will be able to provide a direct test of how corridors function under climatic warming scenarios.

Glossary

Acclimation Acclimatization that occurs in a controlled, experimental setting such as a laboratory (*see* Acclimatization).

Acclimatization Ability of an organism to adjust its phenotype to new environmental conditions over the course of its lifetime given its genotype (*see* Phenotypic plasticity).

Adaptation Beneficial modifications to an organism's phenotype that are caused by heritable changes in its genotype.

Eurythermal Ability to tolerate a wide range of temperatures.

Extirpation Local extinction whereby a group of organisms ceases to exist in a particular location but may still exist in other locations.

Local adaptation Process by which populations of organisms become adapted to their local environment or

ecological niche. Populations that are locally adapted generally exhibit the highest fitness in their native environment and reduced fitness in other, contrasting locations or conditions.

Net primary productivity Rate of production of biomass by plants and other primary producers such as algae. This forms the basis for all food webs.

Ocean acidification Ongoing changes in carbonate chemistry of the Earth's oceans (e.g., decrease in pH and decrease in carbonate ions) caused by their uptake of anthropogenic carbon dioxide from the atmosphere.

Phenotypic plasticity Ability of an organism to change its phenotype in response to changes in the environment.

Resilience Ability of a system to maintain function in the face of disturbance, including recovery from disturbance.

Introduction

Although climate change has quickly become a central concern in the conservation of biodiversity, marine systems have been largely overlooked (Richardson and Poloczanska, 2008). The effects and rates of climate change, however, are just as dramatic in the ocean as on land (Burrows *et al.*, 2011). Marine species and ecosystems have adapted to climate variability throughout geologic history, but the rate of change in climates both now and through the rest of the century is expected to reach or exceed their abilities to respond and persist into the future. In addition, marine communities are faced not only with climate change but also with fishing, habitat destruction, pollution, invasive species, new pathogens, and other anthropogenic impacts, all of which compound the detrimental effects of climate change.

Rising atmospheric carbon dioxide (CO₂) is expected to result in many abiotic changes to the marine environment. At ocean basin scales, numerous long-term changes have already been observed. Global average air and ocean temperatures are increasing, dissolved oxygen levels are decreasing, and global average sea level is rising (IPCC, 2007). In a process called "ocean acidification," elevated CO₂ in the atmosphere is dissolving into the ocean and causing a decrease in pH and carbonate ions. Changes in precipitation, ocean salinity, wind patterns, and aspects of extreme weather, including heavy precipitation and tropical cyclone intensity, have also been attributed to climate change. Besides the ongoing changes that have been detected, other changes are predicted to occur in ocean currents, vertical structure of the ocean, flow of nutrients, and general patterns of variability.

Marine organisms are directly affected by this rapidly changing environment. Potential responses for species to climate change can be broadly grouped into four general categories (*sensu* Fuller *et al.*, 2010; Parmesan, 2006): (1) they move in pace with the changing climate (e.g., range expansions, colonization of new niches, migration into novel habitats), (2) they adjust to new environmental conditions with their existing abilities (acclimatize), (3) they evolve new abilities to tolerate the climate, or (4) they face extinction or extirpation. Species may also have multiple and simultaneous responses (O'Connor *et al.*, 2011).

In this chapter, we explore the state of knowledge regarding both the impacts of climate change on marine species and the range of strategies proposed for marine conservation. For the sake of organization, we present impacts separately in terms of physiology, population abundance and distribution, evolution, and communities, though in reality there are important interactions among these impacts. We then discuss conservation strategies as integrated responses to help marine ecosystems cope with and adapt to the coming challenges of climate change. For further information, we direct readers to a number of well-crafted reviews over the past two decades (Fuller *et al.*, 2010; Brierley and Kingsford, 2009; Fields *et al.*, 1993; Hoffmann and Sgro, 2011; Harley *et al.*, 2006).

Physiological Impacts

How will coming abiotic changes affect the physiology of organisms living in the sea? In this section, the focus will be on

how two commonly studied aspects of climate change affect the physiology of marine animals: rising seawater temperatures and ocean acidification. By examining how marine organisms respond to these two climate stressors, we gain a better understanding of the types of physiological traits that are most important. Determining the capacity of organisms to acclimatize to environmental change is also key to understanding how populations and communities will respond to climate change.

Rising Temperatures

The vast majority of marine fish and invertebrates are “ectotherms,” meaning that their body temperature fluctuates with that of the surrounding environment. Ectotherms are limited in their ability to internally regulate temperature, thus making them highly vulnerable to global warming. Marine ectothermic fishes and invertebrates have certain temperature ranges in which their performance is maximal. For example, Atlantic cod (*Gadus morhua*), an important fisheries species, grows and reproduces best within a temperature window close to $\sim 10^{\circ}\text{C}$ (Pörtner *et al.*, 2008). In general, as temperatures warm, growth and metabolic rates increase. This may be initially beneficial, but further increases in temperature will push fish outside of their optimal window and lead to excessive metabolic demands. Beyond optimal temperature thresholds (termed “pejus temperatures”), cod struggle to maintain cardiac function and respiration. This leads to decreased swimming performance and less energy available for growth and reproduction (Pörtner and Knust, 2007). As temperatures increase even further, enzymes and other proteins within tissues and cells lose their conformational shape and fail to catalyze reactions (termed “denaturation temperatures”). Exposure to temperatures beyond this denaturation threshold can only last a short amount of time before mortality ensues. During this time, animals can turn to cellular defenses (including heat shock proteins and antioxidants) to temporarily prevent molecular malfunction until they return to cooler waters. The generalized scheme of thermal windows defined by optimal, pejus, and denaturation thresholds applies to both fish and invertebrates (Pörtner and Farrell, 2008).

To a limited extent, organisms can also adjust their thermal windows up or down in response to the temperatures they have experienced over longer time periods (for example, weeks or months). This process is called “acclimatization.” It remains uncertain whether animals can adjust their thermal window far enough and fast enough upward to keep pace with climate change without negative impacts on other aspects of their physiology (e.g., Donelson *et al.*, 2010).

A species’ thermal history can often help scientists determine how susceptible species will be to climate change. For example, animals already living near their thermal limits (the edges of these windows) may be most at risk (Somero, 2010). A recent study on a marine in-shore fish called the red moki (*Cheilodactylus spectabilis*) in the Tasman Sea showed that temperatures may have already reached levels associated with negative metabolic effects (Neuheimer *et al.*, 2011). Increasing temperatures were correlated with increased growth for populations in the middle of the species range, but warming

appeared to cause reduced growth rates for populations at the warm northern edge of the species’ distribution. This pattern indicates that temperatures may have already reached levels associated with high metabolic costs at this northern edge (Neuheimer *et al.*, 2011). If warming continues, a range contraction may be inevitable for this species. A suite of studies on intertidal porcelain crabs (*Petrolisthes* spp.) and marine snails (*Chlorostoma* spp.) showed that the most heat-tolerant species have little ability to increase their lethal and sublethal thermal tolerance windows through acclimatization (reviewed in Somero, 2010). In contrast, an in-depth examination of acclimatory and adaptive capacity of thermal tolerance limits in European diving beetles (Calosi *et al.*, 2008) found the opposite trend. Organisms with the highest upper thermal tolerance limits demonstrated the greatest capacity for acclimation. Contrasting findings such as these mean that broad generalizations regarding thermal tolerance and responses to future rapid climate change should be treated with caution for the moment.

Animals living in narrow, constant thermal habitats are also thought to have relatively low capacity to shift their thermal windows upward. For example, antarctic nototheniid fish (*Trematomus bernacchii*) have lived in a cold, constant environment for more than 15 million years and have very limited tolerance for higher temperatures. Some antarctic invertebrates have likewise shown limited ability to acclimatize to warmer temperatures (Peck *et al.*, 2004). These fish and invertebrates do not have the option of moving to a cooler location. Like the crabs and fishes described previously, these fish may also be the losers in a warmer world.

In contrast, animals living in fluctuating environments may be climate change winners. For example, a set of studies of reef-building corals from American Samoa found that corals from a highly variable environment may be acclimatized (and locally adapted) to tolerate greater levels of environmental stress when compared to corals from more stable neighboring areas (Barshis *et al.*, 2010; Smith *et al.*, 2008). Several physiological mechanisms have been described to explain this, including changes in the symbiotic algae that live within corals and a greater production of stress proteins and antioxidants during extreme heat stress events (Barshis *et al.*, 2010; Smith *et al.*, 2008). Whether marine organisms living in fluctuating environments are generally more tolerant to temperature stress has yet to be determined.

Ocean Acidification

Compared to temperature, less is known about the complex effects of ocean acidification on marine animals, not to mention the combined effects of temperature and changing ocean chemistry. Research to date suggests that ocean acidification has three primary physiological effects on marine animals. First, decreased carbonate ion concentrations make the calcification process more difficult for calcifying organisms such as corals and shellfish. These organisms require carbonate ions to build their shells and skeletons. Second, lowered pH and a greater amount of dissolved CO_2 in the water could affect acid–base regulation and metabolic rates as well as other physiological processes. Third, greater amounts of

dissolved CO₂ could alter the ability of primary producers to photosynthesize.

Most of the research so far has focused on negative calcification effects, and this research generally suggests that many calcifiers will be “losers.” A decrease in the concentration of carbonate ions has been correlated with reduced calcification in several organisms, including abundant planktonic species (e.g., coccolithophores, pteropods, and foraminifera) and benthic invertebrates (e.g., coral, calcifying algae, mollusks, echinoderms) (Erez *et al.*, 2011; Guinotte and Fabry, 2008; Raven *et al.*, 2005; Fabry *et al.*, 2008). Marine calcifiers are thought to be highly sensitive to acidification not only because fewer carbonate ions in the water make calcium carbonate formation more difficult, but also because many calcifiers have low capacity for acid–base regulation (Hofmann and Todgham, 2010; Pörtner *et al.*, 2005). Calcification is energetically costly (Palmer, 1992) and appears to be one of the first physiological processes to be slowed down under conditions of acidification (Todgham and Hofmann, 2009). However, some species are able to maintain their calcification rates when supplied with enough energy (i.e., food and nutrients) (Cohen and Holcomb, 2009). Because the cellular mechanism of calcification in most of these animals is still unknown and because responses can vary across different life stages, this story is far from clear. Some marine calcifiers are affected much less than others, and even closely related species can exhibit quite different responses (Dupont *et al.*, 2010).

The role of pH is diverse in physiological processes, ranging from maintaining the proton gradients that allow organisms to produce energy from food (respiration) and fix carbon (photosynthesis) to affecting the functions of whole organisms. As CO₂ levels in the ocean increase and seawater pH decreases, the ability of organisms to maintain extracellular pH homeostasis (acid–base balance) may be compromised. In sensitive animals, increases in the amount of CO₂ may result in depressed metabolic rates, reduced ion exchange, and lower protein synthesis rates (Pörtner *et al.*, 2005). Overall, this could shift a species’ metabolic equilibrium and slow its growth. Sensitivity to elevated CO₂ levels is lower in fish than in most invertebrates, especially those fish with higher metabolic rates. Fish may be less sensitive because they have a more advanced oxygen transport system and because vertebrates have a greater ability to regulate ion exchange than invertebrates (Pörtner *et al.*, 2005). For example, even moderately higher amounts of CO₂ in the water can cause abnormal increases in the acidity of body tissue and fluids (acidosis) of some invertebrates, including some squid and mussel species, and it may contribute to their low resistance and relatively high mortality (Pörtner *et al.*, 2005). In contrast, with the same levels of CO₂ in the water, most fish can return the pH of their fluids to normal using compensatory mechanisms. Thus, the vast majority of acidification studies focus on invertebrates or on early developmental stages in fish before they gain these compensatory mechanisms.

In contrast, some physiological processes such as photosynthesis may benefit from increased levels of CO₂ in the water. For example, certain species of sea grass have increased photosynthetic rates and reduced light requirements when CO₂ levels are high (Guinotte and Fabry, 2008; Zimmerman

et al., 1997). However, most marine producers have evolved carbon-concentrating mechanisms that allow them to cope with the relatively low levels of available CO₂ in seawater (Reinfelder, 2011). Although CO₂ does not generally limit photosynthesis in marine primary producers now, it is possible that higher CO₂ concentrations in the future will reduce the energetic and nutrient costs of carbon-concentrating mechanisms and that this could then modulate primary production and species composition of phytoplankton communities in the future (Reinfelder, 2011).

Finally, the interaction and synergism of climate change effects will undoubtedly produce new responses that may prove to be more deleterious than either stressor alone. For example, synergistic stressors such as ocean acidification and hypoxia may narrow thermal windows, depending on species-specific sensitivities (Pörtner and Farrell, 2008). In other cases, multiple stressors could cancel out the negative effects of each other (Crain *et al.*, 2008). Research into the effects of multiple stressors is only beginning but promises to be a fruitful area for a better understanding of the physiology of climate change.

Impacts on Distribution and Abundance

Many conservation and management efforts, including fisheries management programs, are concerned with maintaining the abundance and distribution of populations. A population responds to climate by integrating both the physiological impacts described previously and the changing species interactions and evolutionary forces described later in this chapter. Responses can include changes in rates of growth, reproduction, mortality, dispersal, or timing of major events. Together, these responses determine population abundance and distribution.

Impacts on Abundance

As a starting point for understanding how populations will respond to climate change, we can attempt to scale up from the physiological effects of temperature, acidification, oxygen, and other predicted changes. For example, laboratory studies have shown that eelpouts (*Zoarces viviparus*) are physiologically limited and that the growth rates of individual fish decline above 17 °C (Pörtner and Knust, 2007). These effects can also be detected at the population level. In the Wadden Sea where these fish live, mortality increases and population abundance declines above 17 °C (Pörtner and Knust, 2007), suggesting that further warming will drive this population toward extirpation.

Larvae of marine organisms appear particularly sensitive to environmental conditions, and replenishment may be the first population-level process that declines when conditions worsen. Larval survival is tied to temperature (Pepin, 1991) and CO₂ concentration (Munday *et al.*, 2010), and successful recruitment back to suitable adult habitat often depends on oceanographic conditions (Roughgarden *et al.*, 1988). In coastal upwelling zones of the ocean, including the coast of California, recruitment of species like barnacles is tied to relaxation of the winds that otherwise drive currents away from

the coast (Roughgarden *et al.*, 1988). Changes to upwelling, which are a likely consequence of climate change, are therefore likely to have important impacts on population replenishment by larvae (Harley *et al.*, 2006). In spite of the sensitivity of larvae to climate, however, declines in population abundance will lag further behind because adults can continue to survive in a given location for many years, particularly among long-lived species.

It is also important to realize that changes in growth, mortality, and reproduction can compensate for each other, thereby mitigating the immediate effects of climate change. For example, higher temperatures can negatively affect survival and recruitment, but abundance can nevertheless stay the same if individuals grow to reproductive age more quickly (Doak and Morris, 2010). Care must therefore be taken before directly projecting from physiological studies to population-level impacts without carefully considering the full range of processes that affect populations.

Other population-level impacts difficult to predict from physiological studies are related to phenology, or the seasonal timing of ecological events. The life cycles of fishes are often synchronized to the seasonal production of plankton so that offspring have sufficient food for growth and survival. Research in the North Sea, however, has shown that fish larvae appear earlier in warm years, whereas many lower trophic level species (e.g., some phytoplankton) do not change their timing, likely because they are cued to light levels (Edwards and Richardson, 2004). Mismatches between reproduction of fish and the availability of their planktonic food can cause dramatic decreases in abundance, as has been documented for Atlantic cod (*Gadus morhua*) (Beaugrand *et al.*, 2003). More broadly, populations are affected indirectly by changes to the productivity, structure, and composition of ecosystems that provide food and shelter necessary for growth and survival (see the section “Community Impacts”).

One of the most comprehensive efforts to consider the range of climate factors that impinges on population abundance has been undertaken for tuna. A valuable fisheries species, these predators undergo oceanwide migrations every year in search of food and suitable reproductive habitats. By building a population dynamics model on top of global projections for temperature, oxygen, and ocean biogeochemistry, Lehodey and colleagues (2010) predicted that spawning habitats for bigeye tuna (*Thunnus obesus*) would move poleward and toward the eastern tropical Pacific, that access to food would improve in some areas, and that adult survival would decline. Overall, the model predicted stable populations for decades but a declining abundance at the end of the 21st century.

Impacts on Distribution

Even if populations decline in some places, they may flourish in others or colonize new, previously unoccupied habitats as conditions become more favorable. Extinction within “trailing edge” populations or colonization of “leading edge” populations – or a combination of the two – creates range shifts. Despite little attention to range shifts in the ocean during the beginning of climate change research, range shifts appear to be

a particularly common and dramatic occurrence in the marine realm (Sorte *et al.*, 2010). Historical surveys have revealed species shifting an average of 19 km yr⁻¹ (Sorte *et al.*, 2010), which is an order of magnitude faster than rates observed on land (Parmesan and Yohe, 2003). Species also move deeper as temperatures warm, with rates of 3.6 m per decade measured among North Sea fishes (Perry *et al.*, 2005; Dulvy *et al.*, 2008). Of 129 geographic shifts in marine species that are known so far, 75% are in poleward directions, as would be predicted from widespread warming (Sorte *et al.*, 2010).

On the west coast of North America, however, species such as blue mussels (*Mytilus* spp.) have instead moved toward the equator in recent years (Hilbish *et al.*, 2010). Although at first counterintuitive, this shift is entirely consistent with species ranges that respond to climate. This shift appears to be driven by temporary regional cooling in the California Current ecosystem caused by decadal-scale climate oscillations. This and other examples showing rapid responses of marine species ranges to climatic conditions (e.g., Fisher *et al.*, 2008) suggest that marine species distributions respond quickly and perhaps predictably to climate. Taking this hypothesis to its logical end would predict a massive redistribution of marine species toward the poles and away from the tropics over the coming decades (Cheung *et al.*, 2009). Not all marine species can move quickly in response to climate, however. Some fishes and invertebrates spend very little time dispersing as larvae and move little as adults (Kinlan and Gaines, 2003; Shanks, 2009). Whether these and other species will keep up with climate change remains an important question.

Other researchers have also pointed out a number of factors that make predicting future geographic shifts in species ranges more complicated than simply mapping future temperatures. At one level, local microclimates can diverge substantially from regional averages, so there are no simple latitudinal gradients in temperature for species ranges to follow. For example, intertidal mussels experience hot midday air temperatures only when the tide is low, and the timing of tides on the west coast of North America is such that sites in Washington and Oregon experience more extreme temperatures than many in California (Helmuth *et al.*, 2002). Because adult mussels are sedentary, these microclimates are crucial for determining growth and survival. Local microclimates may be less important in deeper waters where oceanic mixing ensures greater homogeneity, but finding appropriate methods to predict local climates in the ocean remains an area of important research (Stock *et al.*, 2011).

Range shifts for species are also unlikely to be smooth transitions over time that track closely with mean climate conditions. Instead, punctuated transitions occur when extinctions and colonizations are driven by stochastic extreme events of large effect. Although air temperatures have warmed gradually over the past 30 years at Tatoosh Island, the upper distributional limit of an intertidal red alga moved downward in large, punctuated steps (Harley and Paine, 2009). These extirpations at the species’ upper limit only occurred during summers when temperatures were high and seas were calm. Without both factors at the same time, no change in distribution occurred. Colonization of new habitat is also likely to be highly stochastic (Clark *et al.*, 2001). This is especially true in the ocean, where organisms rely on highly variable

oceanographic currents to deliver their larvae to new habitats (Siegel *et al.*, 2008).

In addition, species ranges are not determined solely by temperature. Coastal mosaics of ocean acidification are likely to shape the distribution of calcifying species in particular (Feely *et al.*, 2008), whereas changes to the extent of oxygen minimum zones will affect many fishes (Cheung *et al.*, 2011). Changes to runoff from land (driven in part by changes to precipitation), storm frequency, and sea-level rise will also be important for intertidal and near-coastal species.

Finally, ecological processes beyond simple tolerance for climatic conditions will be critical considerations when trying to project future species ranges. From theory and empirical studies, we know that species ranges can be set by currents (Gaylord and Gaines, 2000), habitat availability (Gilman, 2006), or species interactions (Harley, 2003) in addition to climate conditions. Research, however, is needed to understand how important these processes are for predicting future changes to species distributions.

Evolutionary Impacts

The ocean is as varied in environmental conditions as it is vast. In response, marine species have evolved complex mechanisms of survival, physiological tolerance, communication, navigation, and food production and capture. A central evolutionary concern is that the current pace of anthropogenic climate change is likely to be faster than the evolutionary rate of most species. In other words, environmental shifts will likely outpace many species' abilities to adapt evolutionarily to the new conditions. Whether some species in some locations will be able to adapt, however, remains a fascinating question. Adaptations in response to climate change induced shifts in environment have already been found in a handful of terrestrial species (Bradshaw and Holzapfel, 2006; Hoffmann and Sgro, 2011), but similar examples from the marine realm have yet to be uncovered.

Adaptation in a Changing Climate

Traditionally, the theory of natural selection posits that adaptation occurs in slow, successive steps. An increasing body of evidence, however, has shown that rapid, "contemporary evolution" may be more common than previously thought and perhaps can even occur at a pace similar to expected rates of climate change (e.g., Barrett *et al.*, 2010; Marko, 2004; Hoffmann and Sgro, 2011; Hendry and Kinnison, 1999). For example, Barrett *et al.* (2010) found that cold tolerance in marine sticklebacks underwent a rapid evolutionary shift of 2.5 °C over three generations (~27 months) after transplantation to freshwater, one of the most rapid rates of phenotypic evolutionary change ever observed in a natural population.

In contrast, populations with long generation times, low effective population sizes, and low genetic diversity may not possess the flexibility to adapt over such rapid timescales (e.g., Harley *et al.*, 2006). In the case of the sticklebacks, there have been repeated historical transitions between marine and freshwater habitats over past glacial cycles (McKinnon and

Rundle, 2002) that are likely to have created a high level of standing genetic diversity in these species (P. Shulte, personal communication). Hence, although natural selection may be acting quickly in this system, the evolutionary material that is under selection may have evolved over many thousands of years. Additional studies of contemporary evolution via experimental manipulations (*sensu* Barrett *et al.*, 2010), further inference based on historical records (*sensu* Marko, 2004), and additional contemporary analysis across a variety of taxa will be critical in assessing the capacity of marine organisms to adapt to future climate change more generally.

Local Adaptation

Understanding local adaptations of populations to specific environmental conditions and ecological roles is also an important process to consider when predicting how organisms will respond to future climate change. Equatorial populations of reef-building corals, for example, have higher upper thermal tolerance limits and are genetically differentiated from more southern populations (Smith-Keune and van Oppen, 2006), suggesting that thermal tolerance limits have evolved to match surrounding water temperatures. Local adaptation of upper thermal tolerance limits has also been found in populations of an intertidal snail along the West Coast of the US (Kuo and Sanford, 2009), although in a somewhat different pattern. In the snails, those with greater thermal tolerance limits were found at higher latitudes due to the higher frequency of extreme thermal exposures in northern intertidal locations. This difference between the two studies serves to illustrate the importance of understanding local microclimate and habitat differences and how they relate to environmental selection pressures.

Local adaptation can also have important effects on how genes and phenotypes are distributed in response to climatic changes. If local environmental conditions become more extreme, then populations of organisms locally adapted to historically extreme conditions (e.g., Barshis *et al.*, 2010) may serve as sources of genetic material for locations that only recently shifted to more stressful environmental conditions. Thus, flow of locally adapted genes could provide susceptible populations with the genetic material necessary to adapt to climate change impacts. Alternatively, local adaptation may restrict the ability of certain populations to withstand climate change because genotypes specifically tuned to local environmental conditions may not be capable of surviving additional perturbation caused by global climate change. It also remains difficult to assess whether physiological differences across species ranges are the result of local adaptation or phenotypic plasticity (Sanford and Kelly, 2011), and conservation strategies may differ, depending on the mechanism involved.

Genetic Diversity and Climate Tolerance

Evolutionary theory predicts that peripheral populations in a species' range are likely to contain lower genetic diversity and higher genetic differentiation due to greater distance and smaller effective population size relative to more central

populations (Eckert *et al.*, 2008; Wulff, 1950). This suggests that the populations at the edges of ranges should be less able to adapt to rapid changes in environmental conditions. Indeed, Pearson *et al.* (2009) found that populations at the southern edge of the range of *Fucus serratus*, an intertidal brown alga, showed a greater susceptibility to desiccation and increased heat shock response than their geographically central conspecifics. This was interpreted as increased cellular stress when exposed to heat shock and decreased resilience to environmental stressors. However, Sagarin and Somero (2006) found that levels of heat shock proteins in intertidal mussels and snails showed no correlation with position along the species range, but they found a strong positive correlation with local areas expected to have long daytime exposure during summer months. In this case, the extreme environmental heterogeneity in temperature due to the timing of midday tides may explain why edges of populations did not exhibit higher stress responses as compared to more centrally located populations (e.g., Harley and Helmuth, 2003). The general idea that “edge” populations may be the first to face local extinction must be carefully considered in light of environmental heterogeneity.

Community Impacts

All species are embedded in communities governed by complex webs of species interactions. Although much research about climate change has occurred on a species-by-species basis, it is important to consider how the impacts of climate change on individual species and populations will translate to the broader community and ecosystem. The effects of climate change on a species or population can indirectly affect many other organisms through species interactions, causing cascading impacts on the community structure and function. In addition, interactions among species can either worsen or ameliorate the effects of climate change on a sensitive population. An integrated understanding of the concepts covered in previous sections is needed to predict how marine communities and ecosystems will be impacted by climate change. Differences in physiological tolerance and adaptive capacity among species can cause a restructuring of ecological communities through altered composition and interactions among species. At a global scale, these changes can cause shifts in the productivity, trophic structure, and resilience of marine ecosystems.

One of the clearest impacts of climate change on a community will occur if habitat-forming species are affected. Habitat loss caused by climate change will also result in the loss of the many species reliant on these habitats. For instance, corals are the biogenic habitat formers of coral reef ecosystems, and repeated bleaching events associated with warm temperatures cause both coral mortality and local extirpations of species that rely on live corals (e.g., Graham *et al.*, 2006; Knowlton, 1992). A sharp decline in corallivorous and planktivorous fish that rely on live coral, for example, has been reported shortly after bleaching events (Graham *et al.*, 2006).

Furthermore, climate change is predicted to cause a shift from branching corals with high structural complexity to massive and encrusting corals due to these species' differential

susceptibility to climatic stressors (Loya *et al.*, 2001). A reduction in structural complexity increases competition for remaining habitat and increases predation on small coral reef fishes that use the reef for protection, both of which lead to a dramatic decline in fish abundances (Graham *et al.*, 2006). In addition to coral reefs, many marine communities are also built around biogenic habitat formers that have shown sensitivity to increased temperature or acidification, including kelp forests (Schiel *et al.*, 2004), mangroves (Alongi, 2008), and oyster reefs (Talmage and Gobler, 2011). Sea ice is also an important habitat for numerous species, from zooplankton to polar bears (Atkinson *et al.*, 2004). Much like the response of sensitive biogenic habitat formers, the melting of sea ice will result in a loss of the species reliant on this habitat (Atkinson *et al.*, 2004).

Climate change can also have cascading impacts on the community via its effects on other important species, besides those important to habitat formation. For example, many marine communities have strong trophic cascades where a single species plays a disproportionately strong role in structuring the abundance, distribution, and behavior of other species (Shurin *et al.*, 2002; Paine, 1966). A keystone predator in rocky intertidal communities, the seastar *Pisaster ochraceus*, is known to set the lower distributional limit of mussels (Paine, 1966). Ocean acidification and increased temperatures increase the growth and feeding rate of this species, which in turn reduces the abundance of mussels and the many associated species that grow within mussel beds (Sanford, 1999; Gooding *et al.*, 2009).

In contrast, climate change could in some cases shift the competitive balance away from the keystone or competitive dominant species. For example, ocean acidification enriches macroalgal growth at the expense of a competitively dominant coral species *Acropora* sp. (Diaz-Pulido *et al.*, 2011). This could drive a shift from coral-dominated to algal-dominated reef ecosystems, which would have cascading impacts on a multitude of coral reliant species (Mumby *et al.*, 2007; Anthony *et al.*, 2011).

Much attention has also been given to environmentally driven changes in oceanic primary productivity (the production of biomass through photosynthesis) and how these changes will travel through food webs with climate change (Brander, 2007). Net primary productivity is affected by the availability of light and nutrients, which are in turn affected by dust, runoff, ocean mixing, cloud cover, and the solar cycle. Sea surface warming causes increased stratification of the ocean with warmer waters on top and cooler water below. This process prevents the nutrient-rich deep waters from mixing into the upper, light-rich zone where photosynthesis can occur (Sarmiento *et al.*, 2004). The decrease in global productivity from 1997 to 2006 was associated with warmer surface waters, particularly in low-latitude, stratified oceans (Behrenfeld *et al.*, 2006), suggesting there will be lower productivity with climate change. However, patterns in productivity differ geographically (Sarmiento *et al.*, 2004; Richardson and Schoeman, 2004). For example, phytoplankton abundance increased from 1958 to 2002 as waters warmed in the northeast Atlantic where nutrients were abundant but decreased in southern regions where nutrients were more rare (Richardson and Schoeman, 2004), suggesting

productivity hot spots may shift with climate change. Reductions in productivity and shifts in the location of productivity hot spots have important implications for communities and ecosystems, including important fishery species. For example, reductions in the recruitment of Atlantic cod (*Gadus morhua*) and abundance of Atlantic salmon (*Salmo salar*) have been correlated with climate-associated changes in the plankton community (Beaugrand *et al.*, 2003; Beaugrand and Reid, 2003).

In addition to changes in productivity, the trophic structure of marine food webs might shift toward stronger control by consumers in a warmer ocean (Moran *et al.*, 2010; O'Connor *et al.*, 2009). The metabolic theory of ecology predicts that as temperatures increase, metabolism and feeding rates of consumers will increase. A consequence may be that plant-herbivore interaction strengths will also increase. Plant-herbivore interaction strengths are stronger in warmer conditions (Pennings and Silliman, 2005), suggesting there may be stronger consumer control of marine ecosystems under conditions of climate change (López-Urrutia *et al.*, 2006; O'Connor *et al.*, 2009; Moran *et al.*, 2010). Stronger consumption could offset any increased primary productivity associated with warmer, well-mixed waters in nearshore ecosystems.

In addition to the strong effects of changes to primary productivity or keystone species, numerous weak interactions among the hundreds of other species can influence the community (Berlow, 1999). Because of the complexity of these interactions, it can be difficult to predict the community and ecosystem impacts of climate change from single species experiments. Large mesocosm and natural experiments are especially insightful in these instances. For example, volcanic carbon dioxide vents off the coast of Italy cause changes in the carbonate chemistry of the seawater similar to those predicted with climate change and ocean acidification (Hall-Spencer *et al.*, 2008). The benthic rocky reef community surrounding the vents suggests that, in extremely acidified conditions, the diverse assemblage of calcifying species (e.g., urchins, coralline algae, and mollusks) could be replaced by low-diversity communities that lack important calcifying species and that are dominated by fleshy algae and a few invertebrate species (Hall-Spencer *et al.*, 2008). Decreased abundance of calcifying species has also been reported in mesocosm investigations of acidification on coral reef ecosystems (Kuffner *et al.*, 2008).

Range shifts of marine populations will also influence community composition through species introductions and local extirpations (Barry *et al.*, 1995; Southward *et al.*, 1995). If the invading species are strong competitors or predators, species introductions can significantly alter community and ecosystem function (Zeidberg and Robison, 2007; O'Connor and Crowe, 2005). For example, the sea urchin *Centrostephanus rodgersii* (Diadematidae) has recently expanded its range poleward from mainland Australia to Tasmania. *C. rodgersii* is known for causing large barrens and sharp reductions in biodiversity in kelp forests. The increasing rate of species introductions associated with climate-driven range shifts will create novel communities, and the consequences remain difficult to predict.

At a broader level, ecological communities function as complex adaptive systems that have a certain degree of

inherent resilience (Levin and Lubchenco, 2008), but climate change may overcome this resilience. Generally, resilience is the ability of an ecosystem to maintain its function despite disturbance events, whereas loss of resilience is often associated with abrupt shifts between dramatically different states (Gunderson, 2000; Scheffer *et al.*, 2001; Levin and Lubchenco, 2008). Resilience is often considered to have two components: resistance to change and ability to recover (Levin and Lubchenco, 2008). In ecosystems, these abilities are provided in part by a combination of diversity and redundancy among the components that make up that ecosystem. For example, a diversity of herbivorous fishes and sea urchins graze on algae and prevent coral reefs from being overgrown. Overfishing in parts of the Caribbean, however, created reef ecosystems with low redundancy because, without herbivorous fishes, only urchins were left to feed on algae. The result, as shown dramatically in Jamaica in the 1980s, was that the coral reefs were transformed into algal fields when a disease swept through urchin populations and removed the last effective herbivore (Hughes, 1994). More recent work has shown that a lack of herbivorous fishes allows algae to overgrow reefs and prevent corals from regrowing after catastrophic bleaching driven by high temperatures, whereas the presence of fishes allows the reef to recover (Hughes *et al.*, 2007).

A critical question is whether or where marine communities will be resilient to the impacts of climate change. In the face of a sustained stressor such as climate change, the individual components that make up marine ecosystems will change, but will this alter the overall ecosystem function? For example, many species will be extirpated while new species will colonize local ecosystems as their distributions generally move poleward. If replacement species fill similar ecological roles (e.g., herbivores), the entire ecosystem may prove generally resilient and be able to continue providing the types of goods and services that humans want (Levin and Lubchenco, 2008). Where and under which conditions this is likely to be true remains an open area of investigation. In general, however, ecosystems with a larger number of species appear to be more resilient to disturbance, perhaps because species respond uniquely to disturbances and, in systems where many species fill similar ecological roles, key roles can be maintained even as some species decline (Worm *et al.*, 2006).

Conservation Strategies

The ultimate conservation strategy for marine ecosystems faced by climate change is a rapid and dramatic reduction in greenhouse gas emissions. However, at this point, the ocean will become warmer and more acidic and sea level will rise due to climatic inertia alone, even if action is taken now to reduce greenhouse gas emissions. Therefore, this section focuses on what can be done in terms of local or regional mitigation and adaptation to the effects of climate change.

Conservation of marine ecosystems requires considering the range of factors that species and communities need to persist, from growth and survival to dispersal, reproduction, and preservation of ecosystem function. Given the effects of climate change we expect, conservation strategies can broadly

aim to protect species and assemblages as they currently exist, plan ahead for likely shifts in location and community composition, or attempt to do both. It is important to remember, however, that climate conditions are likely to become unfavorable for certain species and populations in certain locations, and conservation of the current status quo will not be possible everywhere. When and where to focus on mitigating the impacts of climate change on existing species versus planning for and facilitating a transition to new communities of species remains an important question for conservation planning.

One approach is to focus conservation on broad ecosystem properties such as diversity and resilience rather than particular species. In a recent review, Worm and Lotze (2009) argue that high biodiversity can provide resilience against climate change impacts and needs to be an important consideration in management actions. In systems with higher biodiversity, species can exhibit a wider range of responses to climate change. This range both increases the probability that at least some species will continue performing important ecosystem functions and reduces the overall variability of the ecosystem by averaging the responses across many different species (the portfolio effect). Alleviation of other, more targeted stressors such as overfishing, land-based pollution, and destructive resource uses is one strategy to manage for resilience because it protects the redundancy of ecosystem functions and enhances the ability of a given ecosystem to tolerate or bounce back from the impacts of climate change. Flexibility and active experimentation with conservation strategies, termed “adaptive management,” will also be key to ensuring effective marine conservation as new recommendations are generated through research.

Prioritizing Species for Research and the Role of Predictive Modeling

Can we predict which fishes and invertebrates will be the climate change “winners” and “losers”? If so, how can marine managers incorporate this information into policies to protect marine biodiversity? Given limited resources, identification of priority species for climate change research is key to making informed management decisions. Efforts can focus on species that are already known to be vulnerable (e.g., species living close to their environmental limits), species that play key ecological roles such as keystone or foundation species (e.g., corals), and key indicator species that have easily studied and monitored traits relevant to climate change.

Species’ capacity for physiological plasticity and genetic adaptation in response to climate change can also be incorporated into predictive population or community-level models (Chevin *et al.*, 2010). These models can help predict which conservation strategies might be most effective for a particular species or group of species. For example, it has been proposed that reefs with more diverse coral communities should be protected because high diversity is an indicator of ecosystem health and high functional redundancy. In contrast, it has also been proposed that less-diverse communities with a high prevalence of thermally tolerant coral species and symbiotic algae should be protected because these may have

greater tolerance of climate change (West and Salm, 2003). Baskett *et al.* (2010) used a theoretical community-level model that included adaptation and acclimation to show that protection of more diverse coral communities would be more effective for long-term maintenance of coral cover than protection of communities with high abundances of thermally tolerant corals. These types of ecophysiological models can be combined with empirical and observational assessments to help conservation managers decide how and where resources can best be allocated (Dawson *et al.*, 2011).

Marine Protected Areas

One common conservation approach is the use of marine protected areas (MPAs). MPAs are areas of the ocean set aside with limited or no fishing and other uses. Although MPAs do not directly address the threats from climate change, they promote biodiversity and ecosystem resilience in the face of climate change because they reduce some of the other stressors on marine populations (McLeod *et al.*, 2009). For example, herbivorous fish maintain coral-dominated ecosystems by grazing competitive macroalgae. Maintenance of healthy herbivorous fish communities in MPAs can increase the resilience of the coral reef ecosystem by grazing macroalgae and thereby indirectly promoting coral recruitment and growth after an extreme climate event (Mumby *et al.*, 2007).

Planning MPAs for climate change is similar to planning for general conservation, and it is important to consider the principles of representation, replication, and spacing (McLeod *et al.*, 2009). Representation refers to protecting the full range of habitat types within an ecosystem, whereas replication ensures that a catastrophe will not destroy the only protected example of that habitat. Together, representation and replication accomplish the goal of spreading the risk of unexpected events, including extreme climatic events (McLeod *et al.*, 2009). In terms of climate change, it is important that replicated MPAs exist in different climate regimes such that they will not all be hit by the same extreme climate events. After such events, the unaffected MPAs can be important sources of larvae to allow recovery in the affected areas. MPA spacing ensures that protected populations are close enough together so as to exchange larvae, maintain viable metapopulations through larval dispersal, and allow for recolonization after disturbances. General guidelines of 15–20 km spacing or less have been suggested to allow sufficient larval exchange for many fishes (McLeod *et al.*, 2009). Ensuring that MPAs are close together is likely to become increasingly important with climate change because increasing temperatures cause larvae to develop more quickly and to disperse shorter distances (O’Connor *et al.*, 2007).

Although the preding guidelines and considerations are important for MPAs everywhere, a fundamental question remains: where should MPAs be located to promote population persistence in the face of climate change? For this question, it is important to consider not only which populations are likely to persist if protected, but also where those populations will be in the future. This requires an understanding of physiological tolerance limits, population dynamics, community structure, and evolutionary history. Coral reefs in particular

have received substantial attention given the near-term threat posed by climate. Mumby and colleagues (2011) present an integrative modeling approach that selects MPA sites across the Bahamas based on both thermal stress resistance and likely evolutionary scenarios. They find that although it is difficult to pick MPAs that hedge against all potential evolutionary outcomes, 15% of sites were selected in all scenarios, making them high-priority targets for early protection (Mumby *et al.*, 2011). If resources are initially focused on these high-priority sites, effort will be maximized until future research and monitoring sheds light on which additional populations are likely to survive.

Given the rates of geographic range shifts already observed (see Impacts on Distribution, above), future shifts should also be considered in MPA design. For short-term shifts, placing MPAs across relevant environmental gradients will allow populations to move while still staying within an MPA (M. Carr, personal communication). For example, species are likely to move deeper and poleward, and so arranging MPAs to encompass a range of depths and along latitudinal gradients will allow for future shifts. Gradients of wave exposure and upwelling may also be important given projected changes in storms and upwelling intensity and the strong role these factors play in shaping coastal marine communities. Finally, positioning MPAs near undeveloped coastlines will allow intertidal areas to move upward and inland as sea levels rise.

Ecosystem-Based Management

Whereas the implementation of MPAs involves designating specific areas as protected, ecosystem-based management represents an effort to consider and manage all the human activities affecting an ecosystem (McLeod and Leslie, 2009). Such an approach is especially important for mitigating threats that spread easily throughout and between ecosystems, including land runoff and pollution. For example, local ocean acidification can be reduced by preventing the runoff of acidic fertilizers and excess nutrients from land and by reducing the discharge of sulfur dioxide into the air (Kelly *et al.*, 2011).

One form of ecosystem-based management is called “marine spatial planning,” and it involves designation of ocean zones for full development, limited use, conservation, or full protection (Crowder and Norse, 2008). From a conservation perspective, the principles just described for MPAs still apply to marine spatial planning, including replication, representation, size, and spacing of conservation zones and general ecosystem-based management of broader threats (Crowder and Norse, 2008).

Marine spatial planning also introduces new considerations, however, because some full development zones may involve building semipermanent structures. These include oil and gas drilling, mining operations, and wind and wave energy. Once built, many of these structures will last for decades, which is sufficient time for climate change to induce substantial alterations in the marine ecosystem. For example, prime habitats for species could move 100 km north in only a few decades (see the preceding description of range shifts), which would move the ideal locations for both conservation and fishing zones and potentially conflict with existing

development. Considering these future shifts proactively within the framework of marine spatial planning remains an area for further attention.

Fisheries Management

A sustainable fishery requires a persistent and viable population in the wild. The level of fishing that can be maintained depends on the productivity of the population, which is a function of growth rate, reproduction, and natural mortality. These are also the population factors affected by climate, and the level of fishing that is sustainable is therefore likely to change with climate change (Brander, 2007). Reductions in fishing mortality will be necessary for some populations, whereas increases will be possible in others. Determining where, when, and how much to alter fisheries regulations, however, currently presents a major challenge for fisheries science (Peterman, 2009).

As one example of what may happen to future fisheries, a coupled climate-population model for Atlantic croaker (*Micropogonias undulatus*) in the northeastern US suggested that yield from the species could increase 30–100% over the coming century (Hare *et al.*, 2010). This model was developed for a region near the species’ northern range limit, where such effects might be expected. In contrast, one would expect declining fisheries toward the species’ southern range limit. One remaining uncertainty, however, is how much the production of plankton (the source of food ultimately available to fish) will change or even in which direction at a regional level (Sherman *et al.*, 2009; Cheung *et al.*, 2011). No matter what the direction of change, the lesson is clear: past experience will no longer be a good guide to sustainable levels of fishing in the future (Peterman, 2009).

Climate-driven shifts to the geographic ranges of fished species also pose new challenges for regional and international fisheries management (Cheung *et al.*, 2009). As populations move poleward, they are likely to become inaccessible to some fishing ports but move within reach of others. When these ports are in different management regimes, fisheries management may not be ready for the change. The so-called Mackerel Wars of 2010 underscored the fact that such problems are not a distant prediction (Anonymous, 2010). Warming climate has shifted the mackerel fishery north from Britain and into Icelandic waters, sparking an international debate about the fisheries quota that should be allocated to each country, and, in the meantime, allowing more fish to be taken from the population than is likely to be sustainable.

This example demonstrates an important fact: fisheries management is about managing people, not fish. Ensuring a sustainable fishery requires transparent and inclusive institutions that can enforce limits on exploitation, engage stakeholders, and design incentives that align public and private benefits (Grafton *et al.*, 2008). In a changing climate, the need for these institutions is even greater given uncertainty about the magnitude and timing of climatic impacts and the likelihood of difficult transitions within the fishing industry as the available species change. Under traditional fisheries management, climate is rarely considered (Hare *et al.*, 2010; Hilborn and Walters, 1992), but this will have to change rapidly so that

institutions and mechanisms for adjusting fisheries management can be in place before the impacts of climate change become more pronounced. Fisheries science has tried to develop management strategies to deal with climate variability, including reference points, fixed decision rules, and climate regime-specific harvest rates, but implementing them effectively requires close monitoring of both fish populations and the ecosystems they inhabit (King and McFarlane, 2006; Walters and Parma, 1996). Even when impacts cannot be predicted ahead of time, fisheries management can be ready to both detect climate-driven changes and respond with new fisheries management when new conditions require doing so.

Assisted Colonization and Restoration

For some marine species – particularly those most sensitive to climate and those with poor dispersal abilities, such as corals – climate conditions may change much faster than their ability to adapt or disperse to more favorable conditions. In these situations, actively moving the species to more favorable locations may be warranted but should only be undertaken after careful consideration of the costs and benefits. “Assisted colonization,” as it is called, may be a reasonable solution when the risk of extinction due to climate change is high, the translocation of the species is technically feasible, and the probability of success outweighs the ecological and socio-economic costs (Hoegh-Guldberg *et al.*, 2008). The history of marine invasive species provide cautionary tales about needlessly introducing species into new ecosystems (Ruiz *et al.*, 1997). However, introducing species beyond their geographic range but within the same biogeographic province is likely to have fewer consequences because many of the same community members will still be present in the new location (Hoegh-Guldberg *et al.*, 2008). In cases where either assisted or natural colonization is hampered by lack of habitat (e.g., coral reefs for many reef species), construction of artificial habitats may be a temporary solution in the near term (Hoegh-Guldberg *et al.*, 2008).

Research Needs

There is little doubt that effective conservation strategies aimed at mitigating climate change impacts need to be based on sound, robust research. Yet many gaps remain as to how specific species and assemblages will react to climatic shifts, whether multiple environmental stressors will have synergistic effects, how quickly populations can adapt and acclimatize to rapid environmental change, and how best to allocate resources given these uncertainties. Future research needs to focus on filling in these gaps across a wide variety of species in order for conservation to be effective.

For instance, it is likely that increased ocean acidification will have significant impacts, particularly on calcifying organisms, yet long-term studies of response to individual climate change impacts (e.g., ocean acidification, global warming), as well as response to multiple stressors combined, are lacking in the literature (Hofmann *et al.*, 2010; Brown and Cossins, 2011). Similarly, very few studies have attempted

to examine long-term capacity for acclimation and rates of adaptation in the face of climate change (Dawson *et al.*, 2011). In addition, although the need to move beyond predictions is very apparent, experimental evolution research is impractical for nearly all slow-growing, long-lived species. In these cases, careful parameterization of models that consider evolution and phenotypic plasticity can provide valuable insight into the potential responses of marine species in a changing climate (Baskett *et al.*, 2010). Lastly, further efforts to integrate our knowledge of physiology, population biology, evolution, and community interactions into conservation strategies are needed to ensure that present-day efforts remain effective in a rapidly changing climate.

Glossary

Adaptive management Integration of design, management, and monitoring to systematically test assumptions to adapt and learn.

Connectivity Natural linkage between marine habitats which occur via larval dispersal and the movements of adults and juveniles.

Ecosystem-based management (EBM) Environmental management approach that recognizes the full array of interactions within an ecosystem, including humans, rather than considering single issues, species, or ecosystem services in isolation. EBM focuses on cumulative impacts; multiple objectives; embracing change; linkages between species, ecosystems, societies, economies, and institutions; and learning and adaptation.

Ecosystem function Physical, chemical, and biological processes or attributes that contribute to the self-maintenance of an ecosystem (e.g., nutrient cycling, primary productivity).

Ecosystem resilience Ability of an ecosystem to maintain key functions and processes in the face of stresses or pressures, either by resisting or adapting to change; resilient systems are characterized as adaptable, flexible, and able to deal with change and uncertainty.

Ecosystem services Benefits people obtain from ecosystems; include the provision of food, water, timber,

fiber, and other resources; the regulation of floods, disease, wastes, and water quality; the support of cultural practices, including recreation, religion, and art; and the maintenance of biological processes through such phenomena as soil formation, photosynthesis, nutrient cycling, and so on.

Ecosystem “goods” include food, medicinal plants, construction materials, tourism and recreation, and wild genes for domestic plants and animals.

Marine protected area (MPA) Clearly defined geographical space recognized, dedicated, and managed through legal or other effective means to achieve the long-term conservation of nature with associated ecosystem services and cultural values.

Marine reserve Subset of an MPA and an area of ocean completely protected from all extractive and destructive activities.

MPA network Collection of individual MPAs operating cooperatively and synergistically – at various spatial scales and with a range of protection levels – to fulfill ecological aims more effectively and comprehensively than individual sites could alone.

No-take area Marine area that is permanently or temporarily completely closed for any form of extraction, and where no disturbance of any kind is allowed.

Introduction

Humans depend on the oceans for food security, shoreline protection, recreational opportunities, cultural heritage, climate regulation, and other services. Despite their tremendous value, the health of the world's oceans has continued to decline due to human activities such as overfishing, pollution, and climate change (Jackson *et al.*, 2001; Worm *et al.*, 2006; Halpern *et al.*, 2008a). These impacts are leading to ecosystem collapses in all the major coastal and ocean regions of the world (Wilkinson, 2004; Hughes *et al.*, 2005; Jackson, 2008).

Over the last several decades, about one-third of coastal and marine habitats, such as mangroves, seagrasses, coral reefs, and salt marshes, have been lost due to human activities (Valiela *et al.*, 2001; Wilkinson, 2004; Duarte *et al.*, 2008; Waycott *et al.*, 2009; Spalding *et al.*, 2010). More than half of the world's fisheries stocks are fully exploited and producing catches at or close to their maximum sustainable limits, and more than 25% are overexploited, depleted, or recovering from depletion (FAO, 2007). Fundamental changes to ecosystem structure, such as changes in species diversity, population abundance, size structure, sex ratios, habitat structure, trophic dynamics, biogeochemistry, and biological interactions, are occurring

worldwide (Lubchenco *et al.*, 2003). These changes affect marine ecosystem function and have critical implications for people that depend on these ecosystems for goods and services (Lubchenco *et al.*, 1995).

Marine protected areas (MPAs) have been identified as one of the most effective tools for conserving marine ecosystems (Kelleher, 1999; Palumbi, 2003). A number of terms are used, often interchangeably, to refer to marine areas that are protected by spatially explicit restrictions, including MPAs, marine reserves, closed areas, harvest refuges, and sanctuaries (Agardi, 2000). In this chapter, an MPA is a “clearly defined geographical space, recognized, dedicated and managed, through legal or other effective means, to achieve the long-term conservation of nature with associated ecosystem services and cultural values” (Dudley, 2008). A marine reserve is a subset of an MPA and is defined here as “an area of the ocean completely protected from all extractive and destructive activities” (Lubchenco *et al.*, 2003).

MPAs may include areas with multiple uses (e.g., fishing, tourism), no-take areas and reserves, or restriction of certain areas to a specific use (e.g., local fishing). MPAs range in size from small marine parks designed to protect endangered or threatened species, unique habitat, or cultural or historical sites to large reserves designed to achieve a range of conservation,

social, and economic objectives encompassing different types of protection (Agardi, 2000). Ecological objectives include protection of critical habitats (spawning aggregations, nursery grounds, areas of high biodiversity, and migration routes), maintenance of ecosystem function, and species protection. Socioeconomic objectives include the protection of commercially valuable species, cultural and historic sites, recreation and tourism sites, and sites important for education or research (Salm *et al.*, 2000). If MPAs are well designed and managed, they have the potential to protect and in some cases restore coastal and marine ecosystems and support communities that depend on these ecosystems.

MPAs are most effective when combined with other management tools such as integrated coastal management, marine spatial planning (MSP), and fisheries management (Salm *et al.*, 2006; Dudley, 2008). MPAs are vulnerable to activities outside their boundaries (e.g., pollution and unsustainable fishing) that can affect species and ecosystem functions within protected areas (Kaiser, 2005). Therefore, integrated coastal management to control land-based threats such as pollution and sedimentation and other forms of resource management such as fishery management tools (e.g., catch limits, gear restrictions, regulations regarding fishing grounds, fishing seasons; Kaiser, 2005; Keller *et al.*, 2009) are necessary to support the effectiveness of MPAs. MPAs may also be more effective when combined with traditional marine management approaches (McClanahan *et al.*, 2006).

Systems Approach to Marine Conservation

Conservation and fisheries management efforts have evolved over the last decade toward managing systems as opposed to species or specific habitats and managing cumulative impacts. These approaches have been referred to as *ecosystem-based management* (EBM) and ecosystem approach to fisheries (Rosenberg and McLeod, 2005; Levin and Lubchenco, 2008; Palumbi *et al.*, 2008; FAO, 2010). In these approaches, humans are recognized as critical parts of dynamic ecosystems, and the inclusion of the human dimension is now seen as an essential component of effective conservation. Fisheries management has shifted from a focus on maximum sustainable yield of individual species at a single scale to multispecies stock assessments at multiple scales (Pikitch, 2004). EBM supports ecological processes that maintain resources, recognizing the diverse ecological roles of species and habitats at multiple scales (Graham *et al.*, 2003). MPAs protect geographical areas, species, and their biophysical environments and thus can offer an ecosystem-based approach to conservation or fisheries management (Lubchenco *et al.*, 2003).

Evolution of MPA Definitions

The shift toward a multiscale, integrated human–ecological system, and process-oriented perspective (Hughes *et al.*, 2005) is evident in the changing views of MPAs and the call for networks of MPAs worldwide. In 1999, an MPA was defined as “any area of the intertidal or subtidal terrain, together with its overlying water and associated flora, fauna, historical, and

cultural features, which has been reserved by law or other effective means to protect part or all of the enclosed environment” (Kelleher, 1999). In 2008, the World Conservation Union defined an MPA as a “clearly defined geographical space, recognized, dedicated and managed, through legal or other effective means, to achieve the long-term conservation of nature with associated ecosystem services and cultural values” (Dudley, 2008). The explicit reference to conservation for the benefit of people (ecosystem services and cultural values) is highlighted in this latest definition.

Evolution of MPA Objectives

Conservation managers have been called on to consider protection of ecosystem function, structure, and integrity in addition to species and habitat protection (Agardy and Staub, 2006). There has been a shift from the conservation of commercially important species to management of functional groups (i.e., collections of species that perform a similar function, regardless of their taxonomic affinities) supporting processes and maintenance of ecosystem services (e.g., fisheries) (Hughes *et al.*, 2005). The view of no-take areas as primarily fisheries management tools has evolved to include other conservation objectives, including managing biodiversity, trophic structure and function, and ecosystem resilience (Hughes *et al.*, 2005). This shift toward managing ecosystem structure, function, and services emphasizes the importance of ecological roles and species interactions (including humans) for maintaining ecosystem resilience. The effectiveness of MPAs is now evaluated based on their impacts on local communities, in addition to ecological impacts. In addition, integrated studies are developing that assess how ecological performance of reserves is related to both socioeconomic characteristics in coastal communities and reserve design (Pollnac *et al.*, 2010). The results of such studies are useful for highlighting the complexities around human dimensions of marine reserves and informing MPA design and management.

Ecosystem resilience refers to the ability of an ecosystem to maintain key functions and processes in the face of stresses or pressures, either by resisting or adapting to change (Holling, 1973; Nyström and Folke, 2001). Resilient systems are characterized as adaptable, flexible, and able to deal with change and uncertainty (Hughes *et al.*, 2005); thus *resilience* has been identified as a critical component of MPA network design and management. Designing and managing networks for resilience provides MPAs with the best chance to recover from or withstand environmental fluctuations or unexpected catastrophes caused by climate change and other human impacts (West and Salm, 2003; McLeod *et al.*, 2009).

Evolution of MPA Networks

The conservation community and government agencies have called for the establishment of networks of MPAs worldwide. An MPA network is defined as a “collection of individual MPAs operating cooperatively and synergistically, at various spatial scales, and with a range of protection levels, in order to fulfill ecological aims more effectively and comprehensively

than individual sites could alone" (WCPA/IUCN, 2007). MPA networks have also been defined as a "network of people managing the components of individual MPAs and promoting the network's viability and longevity" (Dudley, 2008).

Individual small MPAs may not be effective at conserving biodiversity, fish and invertebrate populations, and the communities that depend on them. Single MPAs large enough to sustain populations and habitats are often impractical due to economic, social, and political constraints (Dudley, 2008). Networks of MPAs have been proposed to help reduce socioeconomic impacts while maintaining conservation and fisheries benefits (PISCO, 2007). Networks are also important for maintaining ecosystem processes and connectivity and supporting ecosystem resilience by spreading the risk of reduced viability of a habitat or community type following a large-scale disturbance or management failures (Keller *et al.*, 2009). The commitment to the establishment of global networks of MPAs has been demonstrated at international meetings such as the World Summit on Sustainable Development in 2002, the World Parks Congress in 2003, and the Convention on Biological Diversity in 2004. The scaling up of individual MPAs to networks demonstrates a systems approach to marine conservation because it allows for the protection of species and habitats in addition to ecological processes, structure, and function.

Evolution of MSP

Over the last decade, marine spatial planning (MSP) has been increasingly recognized as a critical tool to achieve EBM (Douvere, 2008). MSP provides an integrated planning framework that moves away from sectoral management to address multiple objectives related to achieving economic and ecological sustainability and the need to reduce conflicts in marine environment (Agardi *et al.*, 2011). MSP has been defined as a "process of analyzing and allocating parts of the three-dimensional marine spaces to specific uses, to achieve ecological, economic and social objectives that are usually specified through the political process; the MSP process usually results in a comprehensive plan or vision for a marine region" (Ehler and Douvere, 2007). More broadly, the purpose of MSP is to balance demands for development with the need to protect the environment (Douvere, 2008).

Potential benefits of MSP include a holistic approach that addresses social, cultural, economic, and environmental objectives and thus achieve sustainable development; better integration of marine objectives (both between policies and between different planning levels); improved site selection for development or conservation; a more strategic and proactive approach that delivers long-term benefits; management coordination at the scale of ecosystems as well as political jurisdictions; reduced conflicts among uses in the marine area; and reduced risk of marine activities damaging marine ecosystems, including improved consideration of cumulative effects (Gilliland and Laffoley, 2008; Foley *et al.*, 2010).

MSP has been applied to help manage the multiple uses of marine space, particularly in areas where conflicts exist among users and the environment. MSP is central to the management strategy of the Great Barrier Reef in Australia and has also been

applied in other marine areas such as the Florida Keys, Channel Islands, Wadden Sea, North Sea, Irish Sea, and Baltic Sea, among others. MSP is not intended to replace MPAs. MPAs are still recognized as an important tool for managing the marine environment, but they should be considered in the wider context of an MSP strategy that balances the MPAs with economic, social, and biodiversity objectives. By integrating MPA planning in broader MSP and ocean zoning efforts, MSP can help to utilize the benefits of MPAs while avoiding their potential shortcomings (Agardi *et al.*, 2011).

Benefits of MPAs

MPAs have the potential to provide a number of benefits to local communities, fisheries, and the marine environment, including (1) conserving biological diversity and ecosystems; (2) protecting critical spawning and nursery habitats; (3) protecting sites with limited human impact to help them recover from stresses; (4) protecting settlement and growth areas for marine species and spillover benefits to adjacent areas; (5) protecting sites for educating the public about marine ecosystems and threats to them; (6) supporting nature-based recreation and tourism; (7) providing control sites as baselines for scientific research; and (8) reducing poverty and increasing the quality of life of adjacent communities (IUCN-WCPA, 2008). Benefits of MPAs – specifically, marine reserves – have been demonstrated through empirical studies for mollusks, crustaceans, and fishes in habitats ranging from coral reefs, kelp forests, temperate continental shelves, estuaries, seagrass beds, and mangroves (Gell and Roberts, 2003). The following four sections outline the ecological and socioeconomic benefits of marine reserves based on global and regional meta-analyses and site-based studies.

Increases in Size, Abundance, Biomass, Diversity, and Increased Reproductive Potential

Benefits to marine reserves include increases in abundance, biomass, and diversity of many species within reserve boundaries (Table 1), yet the range of responses to reserve establishment is very large (Lester *et al.*, 2009; Gaines *et al.*, 2010a). Kenchington (1990) identifies several classes of species for which marine reserves may not be effective such as species with planktonic larvae and planktonic or pelagic adults (e.g., most phytoplankton and zooplankton species to pelagic fishes with large home ranges). However, these species may have a stage that depends on a nursery area or spawning site, and they could be protected by a reserve, assuming that other life stages outside the reserve are not overexploited (Allison *et al.*, 1998).

Within reserves, individuals can grow larger, live longer, and develop increased reproductive potential and populations increase in size (Bohnsack, 1998). Enhanced production of eggs and larvae within reserves are predicted to result in greater export and settlement of juveniles outside boundaries (Gell and Roberts, 2003). In addition, reserves have helped to restore ecosystem structure and function (Sobel and Dahlgren, 2004; Mumby *et al.*, 2006). However, these benefits do not

Table 1 Global and regional meta-analyses of ecological benefits of marine reserves within reserve boundaries

<i>Indicator</i>	<i>Results</i>	<i>Taxonomic group</i>	<i># Studies/marine reserves analyzed</i>	<i>Source</i>
Biomass	446% increase	Algae, invertebrates, and fishes	124 reserves (global)	Lester <i>et al.</i> (2009)
Density	166% increase			
Individual size	28% increase			
Species richness	21% increase			
Biomass	352% increase	Algae, invertebrates, and fishes	89 studies; 70 reserves (global)	Halpern (2003)
Density	151% increase			
Individual size	29% increase			
Species richness	25% increase			
Biomass	1.9 times higher	Algae, invertebrates, and fishes	30 reserves (global; temperate only)	Stewart <i>et al.</i> (2009)
Density	1.7 times higher			
Species richness	1.5 times higher			
Abundance	25% increase			
Species richness	11% increase	Fishes	19 reserves (global)	Côté <i>et al.</i> (2001)
Abundance	3.7 times higher (for target species)	Fishes	12 studies (global)	Mosquera <i>et al.</i> (2000)
	No change (nontarget species)			
Density	66% increase	Fishes	32 reserves (global)	Molloy <i>et al.</i> (2009)
Density	2.46 times larger	Fishes	12 reserves (regional – European)	Claudet <i>et al.</i> (2008)
Species richness	No effect			
Biomass	2.1 times greater	Fishes	12 reserves (regional – Mediterranean)	Guidetti and Sala (2007)
Density	1.2 times greater			

always occur due to fishers' behavior in response to reserves, fishing regulations outside the reserve, and the regulations regarding activities within and outside the reserve (Gaines *et al.*, 2010b.)

Benefits to Nontarget Species

Recent reviews on the benefits of marine reserves typically focus on benefits to target species as opposed to nontargeted groups such as fish, invertebrates, or algae or corals (Babcock *et al.*, 2010). However, it is important to understand the impacts of reserves on nontarget groups if the goal of protection is to maintain ecosystem structure and function. Studies have documented that nontarget species either do not respond to protection (Jennings *et al.*, 1995; Rakitin and Kramer, 1996) or respond negatively (i.e., reduced abundances in response to increased predation within reserves; McClanahan *et al.*, 1999). Other studies have shown that nontarget habitats improve following protection (Mumby *et al.*, 2005; Shears and Babcock, 2003), where changes in ecosystem structure have been documented due to the restoration of predator populations. For example, in tropical systems, enhanced coral recruitment has occurred following a recovery in herbivores that graze down macroalgae and thus encourage coral settlement (Mumby *et al.*, 2005). In temperate systems in New Zealand, the recovery of lobsters and large fishes led to

predation and declines of sea urchin populations that led to a reduction in grazing and subsequent recovery of kelp forests (Shears and Babcock, 2003). Reserves have the potential to provide useful insights into the indirect effects of overfishing on ecosystem structure and function (Babcock *et al.*, 2010).

Benefits to Adjacent Fisheries

The ability of reserves to provide conservation or fisheries benefits to adjacent waters is highly controversial (Gell and Roberts, 2003; Hilborn *et al.*, 2004; Halpern *et al.*, 2010), yet recent research suggests that higher abundances within reserves can lead to spillover of adults to adjacent waters (Roberts *et al.*, 2001; Abesamis and Russ, 2005; Kellner *et al.*, 2008; Perez-Ruzafa *et al.*, 2008; Halpern *et al.*, 2010). Spillover occurs through the net export of adults and juveniles (spillover effect) and propagules (recruitment effect) (Russ, 2002). The spillover effect operates on local scales (hundreds of meters to kilometers for reef fish), whereas the recruitment effect operates at scales of tens of kilometers (scales of dispersal of pelagic larvae; Palumbi, 2001; Russ *et al.*, 2004). Spillover from reserves may result in economic benefits from enhanced fisheries and tourism (White *et al.*, 2008) yet may take decades to develop fully (Roberts *et al.*, 2001; Russ *et al.*, 2004).

Long-Term Ecological Benefits

Research has shown that fisheries and conservation benefits of marine reserves increase with greater years of protection (Russ *et al.*, 2004; Claudet *et al.*, 2008; Molloy *et al.*, 2009; Selig and Bruno, 2010). To measure the long-term benefits of marine reserves, time-series data are needed to describe ecological changes due to protection and the stability of such changes. Babcock *et al.* (2010) analyzed data from temperate and tropical marine reserves collected on decadal time scales and found that even though most target species showed initial direct effects (e.g., change in abundance, size of individuals, biomass), their trajectories over time were highly variable. The abundance of some target species continued to increase after protection, whereas some leveled off and others decreased over time. Decreases in abundance were likely due to natural fluctuations, fishing impacts from outside reserves, and increases in predation within reserves. Despite these differences, populations of targeted species were more stable in reserves than fished areas, indicating increased ecological resilience (Babcock *et al.*, 2010). Although some benefits are evident shortly after protection (individuals live longer, mortality rates are lower), other benefits take longer to fully develop, such as increases in reproductive output, biodiversity, and stabilization of communities and ecosystem structure and function. Therefore, understanding that indirect effects (e.g., ecosystem-wide recovery) from removal of fishing pressure take time (e.g., > 13 years; Babcock *et al.*, 2010) is essential for managers, policy makers, and communities to have realistic expectations of the benefits of marine reserves.

Socioeconomic Benefits

Although the ecological benefits of MPAs, particularly marine reserves, are well established, there has been less emphasis on

the social and economic benefits to human communities. Further, rigorous policy analyses are lacking that consider the full range of economic costs and benefits of MPAs (Rudd *et al.*, 2003; Pelletier *et al.*, 2005). A limited number of recent assessments review the economic impacts of MPAs but are concentrated in North America, Australia, and Europe (e.g., Carlsen and Wood, 2004; Carter, 2003; KPMG, 2000; Leeworthy and Wiley, 2002; Roncin *et al.*, 2008), thus leaving out areas with the highest tropical marine biodiversity worldwide, such as Southeast Asia and the Pacific.

Socioeconomic assessments of the benefits of MPAs typically differentiate between extractive (e.g., fishers) and non-extractive users (e.g., recreational users such as divers, snorkelers, bathers, ecotourists, and sightseers) because these groups are likely to be impacted differently by the MPA (see Table 2 for a summary of the potential social and economic costs and benefits of MPAs for these user groups). For extractive users, adverse impacts from MPA establishment may include loss of access rights to fishing grounds or increased risk due to traveling farther to access alternative fishing grounds. For a reserve to provide fisheries benefits to human communities, the reserve must lead to a net increase in yield (i.e., increases in harvest must be large enough to compensate for the area removed from fishing). The establishment of a marine reserve may actually reduce fishing opportunity and yield if the fisheries are already sustainably managed (Hastings and Botsford, 1999; Sladek-Nowlis and Roberts, 1999; Ralston and O'Farrell, 2008). The implementation of an MPA can increase costs if fewer fish are available due to harvest restrictions; fuel or labor costs are higher due to traveling farther to fishing grounds, and congestion increases in fishing grounds (Rudd *et al.*, 2003). A number of case studies suggest that fishers perceive the costs of MPAs (in terms of lost harvest) as greater than the benefits provided (e.g., from spillover) (Wolfenden *et al.*, 1994; Sant, 1996; Suman *et al.*, 1999).

Table 2 Summary of potential social and economic benefits and costs of MPAs

Categories	Benefits	Costs
Extractive users (e.g., commercial and recreational fishers)	Increase in catch (and associated income) Enhanced catch variety (greater species variety, greater frequency of older/larger fish)	Decrease in catch (and foregone fishing income) Crowding of displaced effort User conflicts Higher costs associated with choice of fishing location Increase in safety risks
Nonextractive users (e.g., divers, tourists)	Maintain species diversity Greater habitat complexity and diversity Higher density levels of marine species Enhanced recreational opportunities (e.g., scuba, snorkeling) Research opportunities Protection of other ecosystem services (e.g., coastal protection from erosion and storm surge by healthy reefs)	Damage to marine ecosystem Loss of traditional fishing community
Management	Savings in enforcement costs over nonspatial management Revenues derived from charging users of the MPA Scientific knowledge Hedge against uncertain stock assessments Educational opportunities	Increase in monitoring and enforcement costs Direct costs of setting up MPA Costs of compensatory measures for displaced activities Foregone income from resource extraction (oil, gas, and mineral exploration, and bio-prospecting) Increased congestion and possibly degraded ecosystem if MPA is not well managed due to increased use

By contrast, costs may be lower for fishers due to steady and reliable spillover to adjacent fishing grounds and enhanced catch variety (Sumaila, 1998; Roncin *et al.*, 2008). The fishing benefits of MPAs are challenging to assess because fish mobility between reserves and open areas to fishing are often poorly documented and because MPA benefits to fishers are highly dependent on the level of fishing in open areas (Roncin *et al.*, 2008). Thus, the economic value of spillover depends more on fishers' behavior and the cost of fishing as opposed to biological factors (Rudd *et al.*, 2003).

For nonextractive users, MPAs are likely to improve the quality of the marine ecosystem within the MPA that may be valuable to visitors (Rudd and Tupper, 2002). Because marine reserves support increases in the size and abundance of many species within reserve boundaries (Halpern, 2003) and recreational users such as snorkelers and divers prefer viewing larger and more abundant species (Williams and Polunin, 2000; Rudd and Tupper, 2002), the profitability of recreational and tourism providers may be increased by MPA establishment (Rudd *et al.*, 2002). Although an increase in visitors may increase revenues, too many visitors could adversely affect marine ecosystems within MPAs, particularly when their activities are not well managed. Further, increases in congestion may result in a decline in people's willingness to pay for wildlife viewing (Rudd and Tupper, 2002).

Economic valuations of MPAs provide valuable cost-benefit analyses and also highlight how the benefits of an MPA may be distributed. For example, the economic value of a healthy Great Barrier Reef to Australia is currently estimated to be around \$5.5 billion Australian dollars annually and is increasing (McCook *et al.*, 2010). This estimate includes only use values (e.g., jobs, tourism, and fishing) and underestimates the total economic value. The costs associated with zoning and management of the Great Barrier Reef Marine Park are significantly less than the estimated economic value of the Great Barrier Reef; management costs are consistently less than 1% of the economic returns (McCook *et al.*, 2010). Similarly, in the Florida Keys National Marine Sanctuary, the management costs of the conservation program represented only 2% of the total benefits derived from the MPA (Bhat, 2003). In a recent economic analysis of 12 marine reserves in Europe, results suggest that the amount of income generated by fishing and diving in the MPA represents 2.3 times the management costs of the MPA (Roncin *et al.*, 2008). An economic assessment conducted for an MPA in Kenya also demonstrated that the income generated from the MPA was substantially higher than the management and opportunity costs for the park; income from the MPA was \$1.6 million annually from tourism and \$39,000 from fisheries compared to management and opportunity costs of less than \$200,000 (Emerton and Tessema, 2001). Economic benefits from the MPA, such as shoreline protection, marine productivity, wildlife habitat and nursery, and cultural and aesthetic values, were not included in this assessment (Emerton and Tessema, 2001) but would have made the estimate of benefits even greater. The valuation demonstrated that some groups (commercial tourism operators) received the main economic benefits from the MPA, whereas others such as the local fishing communities (which had reduced fishing opportunities) and the park office (responsible for managing the MPA) bore the cost. Such analyses provide valuable indications of the equity of

the distribution of MPA benefits that can directly affect compliance and overall protection.

In addition to assessing the economic benefits of MPAs, social benefits should also be addressed. Studies have documented the importance of assessing the perception of people affected by MPAs, as their perceptions affect the degree of support or opposition to the MPA, and consequently the effectiveness of protection (Pelletier *et al.*, 2005). A critical social benefit of MPAs is reducing and anticipating conflicts between different user groups. Much of the world's coastal areas are characterized by conflict between user groups or jurisdictional agencies (Agardi, 2000). For example, recreational use may conflict with shipping and mineral extraction, and commercial and subsistence fishing may conflict with scuba diving and nature-based tourism. In such cases, zoning can be used to accommodate a wide variety of uses and can be used as a tool to settle disputes when they occur (Reynard, 1994; Agardi, 2000). Other social benefits include improving visitors' satisfaction and increasing public knowledge about marine ecosystems and biodiversity (Pelletier *et al.*, 2005). The potential of MPAs to help alleviate poverty in coastal communities dependent on coral reefs has also been acknowledged (Leisher *et al.*, 2007). It is important to note that although MPAs may achieve their biological objectives, they may fail at achieving their social objectives. Therefore, assessments of the social effects of MPAs are critical to determine their long-term benefits (Christie, 2004).

Global Commitment to MPA Establishment

Governments around the world have demonstrated their commitment to conserving coastal and marine ecosystems for the benefit of the communities that depend on them. National leaders have formed regional initiatives to establish networks of MPAs to support fisheries and food security, sustainable tourism, ecosystem services, livelihoods, and cultural heritage (e.g., the Micronesia Challenge, the Caribbean Challenge, the Coral Triangle Initiative, and the Western Indian Ocean Challenge). These Initiatives are critical to building political will to support marine conservation efforts, improved integration with development priorities, and the development of sustainable financing mechanisms (Toropova *et al.*, 2010).

The number and areal extent of MPAs has increased dramatically over the last decade; the current global coverage of MPAs has increased 60% over the last three years and more than 150% since 2003 (Chape *et al.*, 2008). Currently, the total number of MPAs worldwide is about 5878 and covers more than 4.2 million km² of ocean (~1.2% of the global ocean; Toropova *et al.*, 2010). The World Parks Congress in 2003 set a target for conserving 20–30% of the world's oceans, yet the costs of running a global MPA network have been estimated at \$5–19 billion annually (Balmford *et al.*, 2004). Such an effort would require an increase in current areal and financial investment in marine conservation by two orders of magnitude. A recent assessment of the progress toward global marine protection targets identified a mismatch between the resources available and those required to implement and monitor a global network of protected areas (Wood *et al.*, 2008). The authors (Wood *et al.*, 2008) suggest that once a

global network is developed, it is likely to be a compromise between quantity (how closely the targets are met) and quality (how well designed and effectively managed the protected areas are).

MPA Effectiveness

Despite the increases in the total number of MPAs worldwide, it is essential to assess how well these MPAs are meeting their objectives. According to a recent global analysis, 27% of the world's coral reefs are located within MPAs, yet only 6% of these are effectively managed (Burke *et al.*, 2011). Further, nearly half of the MPAs worldwide are ineffective at reducing the threat of overfishing (Burke *et al.*, 2011).

MPA performance is highly variable (Kelleher *et al.*, 1995; Halpern, 2003), and a number of factors have been identified that limit the effectiveness of MPAs in conserving biodiversity, maintaining fisheries, or providing additional ecosystem services to human communities. Some have suggested that social and political factors, as opposed to biological factors, are the primary determinants of MPA success or failure (Kelleher and Recchia, 1998; McClanahan, 1999; Mascia, 2003; Leisher, 2008). For example, some MPAs are ineffective because the management framework is ignored or not enforced (these are referred to as “paper parks”), or they have regulations that are fully and effectively implemented but are insufficient to address the threats within the MPA. Other factors affecting MPA effectiveness include differences in reserve design (e.g., size of no-take and buffer zones; Claudet *et al.*, 2008) or reserve shape (Kramer and Chapman, 1999). The location of MPAs also affects effectiveness; MPAs are often placed in areas where threats are lowest (e.g., large MPAs in remote areas such as the northwest Hawaiian Islands; Burke *et al.*, 2011) and thus may do little to mitigate local threats.

MPAs may function more effectively when devolution of authority for MPA development and management occurs (e.g., from national government to local governments, nongovernmental organizations, and resource users; White *et al.*, 2002). Other factors supporting effectiveness of MPAs include adaptive and participatory decision-making arrangements; clearly defined MPA boundaries; clear, easily understood, and easily enforceable rules; legitimacy of rules and regulations; political commitment and leadership; and collaborative MPA management structures linking resources with local interests and knowledge (Mascia, 2003).

The result of establishing a reserve in one location is that fishing effort simply moves elsewhere, and the reallocation of fishing efforts can have adverse impacts on species and habitats outside the reserve (Hilborn *et al.*, 2004). In places where fishing systems are effective at protecting stock (e.g., through catch, size, and area limits), it is not clear whether establishing MPAs will provide additional benefits (Hilborn *et al.*, 2004). The effectiveness of reserves also varies due to differential responses of species to protection (Micheli *et al.*, 2004; Molloy *et al.*, 2009). Researchers have noted significantly large increases in abundance of some large-bodied commercially important species following reserve establishment (e.g., Russ and Alcala, 1996; Claudet *et al.*, 2008), yet many species respond less predictably to protection (Mosqueira *et al.*, 2000;

Molloy *et al.*, 2009). Although commonly fished predatory species are likely to benefit from reserve establishment, prey species may decline due to trophic cascades (Micheli *et al.*, 2004; Molloy *et al.*, 2009). Research suggests that MPAs are effective at protecting sedentary species, but they are less effective at preserving highly mobile species that may spend considerable time outside MPA boundaries (Kaiser, 2005), although exceptions have been documented (McCook *et al.*, 2010). Therefore, the scales of adult movement and propagule dispersal can be critical to MPA effectiveness. Empirical studies are needed to clarify the benefits of MPAs to highly mobile species, and innovative management approaches are needed to complement strategically placed MPAs to support them (Gaines *et al.*, 2010b).

Role of MPAs in a Changing World: Rising to the Challenge

Climate change impacts are already occurring in coastal and marine ecosystems worldwide and include shifts in ocean current patterns, ecosystem changes (e.g., widespread coral loss from mass bleaching), changes in larval development and transport, and species range shifts and interactions (Wilkinson, 1998; Parmesan and Yohe, 2003; IPCC, 2007; Rosenzweig *et al.*, 2008). MPAs are a core strategy in marine conservation, yet they are geographically fixed and thus poorly suited to accommodate shifts in species ranges and habitats. In addition, most existing MPAs are designed based on current climate conditions. The recognition of their limitations in a changing world has led some to question their relevance as a conservation response in an era of rapid climate change (Araújo *et al.*, 2004; Hannah *et al.*, 2007).

The ability of MPAs to protect ecosystems and species in the face of climate change and other changes (e.g., increasing global population) is debated (Mora *et al.*, 2006; Graham *et al.*, 2007; McClanahan, 2008; Selig and Bruno, 2010). Some researchers suggest that habitat loss (e.g., coral reefs) in response to climate change, storms, and diseases are unlikely to be mitigated by MPAs (Jameson *et al.*, 2002; Aronson and Precht, 2006; Graham *et al.*, 2008). Site-specific studies have suggested that MPAs do not always protect biodiversity better than unmanaged areas in response to climate impacts (Jones *et al.*, 2004; Graham *et al.*, 2007; McClanahan, 2008). Further, some studies suggest that thermal stress can cause proportionally greater coral mortality of protected than unprotected corals (McClanahan *et al.*, 2007; Graham *et al.*, 2007; Graham *et al.*, 2008; Darling *et al.*, 2010). This may be due to the different coral species composition between protected and unprotected sites (e.g., higher abundance of thermally sensitive corals such as *Acropora* and *Montipora* within reserves) (Côté and Darling, 2010; Darling *et al.*, 2010).

Recent global analyses, however, have confirmed that MPAs can be effective in preventing coral loss (coral cover remained constant in MPAs over 38 years, whereas coral cover on unprotected reefs declined; Selig and Bruno, 2010). Surveys in the Bahamas showed significantly higher increases in coral cover in reserve boundaries compared to outside the reserve (Mumby and Harborne, 2010). Mumby and Harborne (2010) suggest that reserves play an important role in increasing coral

reef recovery rates provided that macroalgae have been depleted by more abundant communities of grazers benefiting from reduced fishing pressure, particularly in the Caribbean.

Empirical evidence both supports (Lafferty and Behrens, 2005; Mumby *et al.*, 2006; Babcock *et al.*, 2010) and refutes (McClanahan, 2008) the idea that species and habitats within reserves are more resilient than those outside reserve boundaries (Gaines *et al.*, 2010b). Therefore, additional studies are urgently needed to establish the ability of MPAs to support resilience in a variety of habitats and geographic locations and in response to diverse threats.

To address the challenge of climate change, conservation practitioners and researchers are applying new tools such as ecological forecasting and climate envelope models to identify sites most likely to protect biodiversity in the future and to assess the ability of reserves and networks to protect species under different climate change scenarios (Araújo *et al.*, 2004; Hannah *et al.*, 2007; Hannah, 2008). Researchers have cautioned that the use of these tools is limited by the lack of existing data needed to support the models and uncertainties inherent in climate change projections and most ecological forecasting approaches (Thuiller, 2004; Lawler *et al.*, 2006; Lawler, 2009).

Complementing the new tools to support MPA design, major advances in recommendations for MPA and network design have also occurred over the last decade (Roberts *et al.*, 2003; Halpern *et al.*, 2006; Gaines *et al.*, 2010a), particularly recommendations specifically designed to address climate change impacts (Lawler, 2009; Mcleod *et al.*, 2009). Such principles may include the identification and protection of refuges (e.g., sites resistant to climate change impacts; such sites can provide the larvae needed to reseed areas that succumb to coral bleaching), pathways of connectivity that link these refuges with damaged areas, and measures to build redundancy into networks, thereby ameliorating the risk that climate change impacts will result in irrevocable biodiversity loss (West and Salm, 2003; Mcleod *et al.*, 2009).

Researchers have suggested that more and larger MPAs will be needed in the future to address climate change impacts (Lawler, 2009). Specific recommendations include increasing the size of existing reserves, adding buffers around existing reserves, and adding larger reserves to reserve networks (Halpin, 1997; Noss, 2001). Establishing more and larger reserves may be insufficient to protect biodiversity and maintain ecosystem services if the reserves are not located in the right places; a more strategic approach involves locating reserves so that they capture the most potential for habitat heterogeneity under a variety of climate scenarios (Lawler, 2009), or in places predicted to escape the brunt of climate change (West and Salm, 2003; Mumby and Steneck, 2008; Mcleod *et al.*, 2009; Côté and Darling, 2010). In addition, whereas larger MPAs may provide protection for increased and functional groups, they may not be politically, socially, or economically feasible. Research also suggests that large MPAs may be less effective than other traditional management approaches. For example, traditional management regimes in Indonesia and Papua New Guinea involving periodic closures were significantly more effective than national parks with permanent closures – a more than 40% increase in targeted fish biomass within reserves in traditional management regimes compared

to less than 2% increase in national parks (McClanahan *et al.*, 2006). McClanahan *et al.* (2006) note that whereas large MPAs may provide the best protection for species susceptible to overfishing, traditional management approaches may provide the best solution for meeting conservation and community goals and reversing the degradation of reef ecosystems.

MPA and zone boundaries should be designed to be flexible in space and time so that they can be expanded or contracted, have seasonal or other fixed time limits, or be moved to different levels of protection to help them meet their objectives in response to future changes. Where habitat shifts are predicted, managers should proactively plan for landward migration, particularly in areas where habitats have the potential to expand (e.g., mangrove migration landward in response to sea-level rise). It is important to identify and protect areas likely to serve as refuges in the future (i.e., predictive protected areas; Herr and Galland, 2009) and also areas that have demonstrated resilience to climate change impacts.

Finally, to help MPAs continue to achieve their social, ecological, and economic objectives, adaptive management is essential. Adaptive management refers to the integration of design, management, and monitoring to systematically test assumptions in order to adapt and learn (Salafsky *et al.*, 2001). In the context of MPAs, adaptive management involves the integration of the best available science into MPA strategies and monitoring to systematically test the effectiveness of management methods and refine them over time. Conservation managers should develop management approaches that are flexible and able to incorporate future species and habitat migrations, and they need to apply risk-spreading strategies to ensure the protection of key larvae, species, and habitats. Monitoring should go beyond simply assessing whether current policies are effective (e.g., is biodiversity declining?) and should focus on resolving the underlying causes (e.g., how can we reverse the decline?) (Hughes *et al.*, 2007). Monitoring programs must address thresholds, regime shifts and feedbacks, and the capacity of ecosystems to maintain ecosystem services in response to future changes (Hughes *et al.*, 2007). Understanding how ecosystem services will be affected by climate change is necessary for setting conservation priorities and designing and managing restoration projects (Lawler, 2009).

MPAs have a critical role to play in protecting marine ecosystems and the benefits derived from these systems and in securing the communities that depend on them. There may be trade-offs between MPAs designed for biodiversity, sustainable use, and climate change. Therefore, it is important to include risk assessments, scenario planning, and adaptive management approaches that incorporate these potential trade-offs (Secretariat of the Convention on Biological Diversity, 2009). To be successful in a changing world, MPAs must strive to achieve the complementary goals of maintaining biodiversity, promoting ecosystem values, and enhancing resilience.

Appendix

List of Courses

- Applied Ecology and Environmental Management
- Conservation Biology

- Marine Ecosystem Management
- Marine Protected Areas
- Fishery Management

Glossary

Biodiversity Variety of life forms often expressed in total number of species on a specific spatial scale. Also includes genetic diversity.

Disturbance Events that affect ecosystems and their functioning.

Ecosystem functions Processes of energy exchange in ecosystems such as the production of biomass and the fixation of carbon.

Ecosystem services Ecosystem functions that benefit people.

Facilitation One species benefiting another by mediating stresses.

Niche Position of species in an ecosystem in relation to other species and with respect to resource use, habitat requirement, and so on.

Resilience The potential for recovery of an ecosystem after disturbances.

Outline

The rapid degradation of ecosystems jeopardizes the services they provide. Among the most valuable of these services is protection of coastlines by shoreline ecological communities such as coral reefs, mangroves, and salt marshes. Here we synthesize evidence from multiple sources to evaluate whether aspects of biodiversity may influence the degree of coastal protection afforded by particular coastal ecosystems. This synthesis should empower ecologists, conservation scientists, and practitioners to test for and then harness the unrealized but high yield potential of incorporating biodiversity into coastal defense planning.

Introduction

Ecosystems provide humans with a host of valuable services, including food provisioning, water purification, carbon sequestration, climate regulation, and natural protection (Costanza *et al.*, 1997; Daily, 1997; Barbier *et al.*, 2011). Among the most valuable of these services is protection of coastlines by natural shoreline communities such as coral reefs, mangroves, and salt marshes (MEA, 2005; Barbier *et al.*, 2008). By baffling water movement and dampening potentially destructive waves before they hit the terrestrial shoreline, the biotic structures created by organisms that make up coastal ecosystems reduce flooding and coastal erosion (Das and Vincent, 2009; Koch *et al.*, 2009). These valuable coastal ecosystem services are, however, being threatened because coastal ecosystems are suffering from widespread degradation through habitat destruction and species extinctions and the resultant reduction in biodiversity (Lotze *et al.*, 2006; Byrnes *et al.*, 2007; Worm *et al.*, 2007; Waycott *et al.*, 2009). Meanwhile, we are facing an increasing number of severe storms

(Munich RE, 2011) and accelerated rates of sea-level rise are predicted (Mousavi *et al.*, 2011). Of all natural disasters, flooding events are second only to earthquakes as causes of fatalities and financial losses (Munich, 2010), and future costs for moving and protecting human shoreline communities are expected to be massive (Parry *et al.*, 2009). Consequently, understanding, conserving, and harnessing the full benefits of natural ecosystems for coastal protection is a high conservation priority.

Although the value of nature-based coastal storm protection is increasingly recognized, our understanding of how to value this service remains largely based on simple models that do not account for physical or ecological complexities inherent in coastal ecosystems. Recent research, however, has begun to refine these models, yielding important implications for ecosystem service management strategies. For example, although the potential for a given coastal ecosystem to protect the coastline was traditionally thought to increase linearly with its size, recent work has demonstrated that the quantity of ecosystem services generated, including coastal protection, often varies nonlinearly with ecosystem size (Barbier *et al.*, 2008; Koch *et al.*, 2009). Appreciation of this nonlinearity can guide ecosystem-based land-use planning strategies that successfully integrate development and conservation goals. Despite these advances, scientists have yet to explicitly consider the possible role of other key system characteristics, such as biodiversity within ecosystems, in determining the quantity of coastal protection they provide.

The last 20 years have witnessed an explosion in research dedicated to understanding links between various aspects of biodiversity and ecosystem functioning (Loreau *et al.*, 2001; Balvanera *et al.*, 2006; Cardinale *et al.*, 2006). To date, one of the clearest messages to emerge from this large body of work is that the identity of species (i.e., those with key functional traits that enhance focal processes) within an ecosystem can have

strong influences on basic ecosystem functions such as resource uptake and productivity. Although the identity of species can be a dominant determinant of ecosystem functioning, biodiversity–ecosystem functioning research has also shown that the richness (i.e., number) of biodiversity components (usually species, but also alleles or genotypes) can boost ecosystem functions and, therefore, may also boost associated services (Balvanera *et al.*, 2006; Cardinale, 2011; Tilman *et al.*, 2006). Although the precise ecological mechanisms underlying these effects are still being investigated, there is growing evidence that *niche complementarity* (ecological difference among species such as phenology, response to disturbance, resource use, etc.) plays a key role (Dimitrakopolous and Schmid, 2004; Kahmen *et al.*, 2005; Cardinale *et al.*, 2011). Theory and growing empirical evidence suggest that such ecological differences among species will become increasingly important over large spatial and temporal scales and where more than one ecological function is considered (Gamfeldt *et al.*, 2008; Griffin *et al.*, 2009a; Isbell *et al.*, 2011). Differences among species in their responses to environmental conditions can help to maintain a steady level of ecosystem functioning in the face of environmental changes as different species act as ecological “insurance” (Yachi and Loreau, 2009; Griffin and Silliman, 2011). In addition to increasing the breadth of ecological niches occupied and providing ecological insurance, a greater richness of species also increases the probability that particular key species (and combinations of species) will be present in a community.

A key but as yet largely unmet challenge is to translate known effects of biodiversity on basic ecosystem functions (e.g., primary productivity and nutrient cycling) at local scales to ecosystem services that are provisioned over larger scales and have a direct value to human society (Díaz *et al.*, 2006). In this chapter, we take the first step toward this goal, asking how aspects of biodiversity may affect nature-based coastal defenses. Specifically, we first provide an overview of the history of coastal protection and the increasing appeal of nature-based strategies; we then give examples of how aspects of biodiversity can be important at multiple scales, how ecosystem diversity across landscapes may be key for harnessing synergies, and even how diversity of trophic levels can be important. We end with a call for large-scale experiments and replicated comparative studies to test how diversity within different levels of ecological organization (species, genetic, and ecosystem) impacts coastal shoreline protection.

A Short History of Coastal-Protection Strategies

Human populations are becoming increasingly concentrated in flood-prone areas (e.g., along coasts and rivers; Cohen *et al.*, 1997), and losses of life and property from floods are expected to increase. Therefore, innovative methods for flood protection that maintain access to freshwater or aquatic food resources, while not hindering economic development, are urgently needed. Incorporating naturally functioning ecosystems as part of coastal land-development strategies has emerged as one of the most economically viable and effective ways to defend against floods while maintaining other ecosystem services (Barbier *et al.*, 2008; Feagin, 2008; Gedan *et al.*, 2011).

Historically, flood management was a decentralized effort charged to individuals or small communities, and solutions were often focused more on adapting to periodic flooding rather than flood prevention (Van Koningsveld, 2008). For example, many people living in seasonally flooded areas in the Netherlands and in Southeast Asia and Africa have traditionally restricted their domiciles to mounds or to floating rafts and often have economies that are intertwined with flooding events. In much of the world, however, economic development and technological advancements have led to increased centralization of flood management. Consequently, traditional solutions have become ever more displaced by the installation of complex flood-defense systems that require large financial investments, large-scale construction, and long-term management and maintenance strategies (Duxbury and Dickinson, 2007), and these often come at the cost of ecosystem integrity.

Early efforts to develop flood-management systems were singly focused on preventing floods without consideration of ecological impacts. In the 1970s, however, increasing environmental awareness and a response to more aggressive flood-management approaches led to legislation ensuring that environmental impacts were considered in flood-management activities. In the 1980s, flood-management decisions continued to take environmental impacts into consideration but weighed potential socioeconomic impacts of floods more heavily than environmental impacts when making flood-control decisions (van Koningsveld *et al.*, 2008). It was not until the mid 1990s that integrated and multidisciplinary design and planning efforts began to emerge as policy makers started to fully appreciate that protecting socioeconomic interests was not necessarily in opposition to protecting ecosystems. Indeed, it was during this time that integrated coastal zone management (ICZM) (launched in 1994), was developed as a way to guarantee safety against flooding while maintaining other functions of the coastal ecosystems. Over the past 15 years, managers have begun to fully embrace this integrative planning process, and innovative solutions to coastal flooding such as ‘living shorelines’ (Gedan *et al.*, 2011; Scyphers *et al.*, 2011) and ‘building with nature’ (Borsje *et al.*, 2011) have emerged that simultaneously enhance the protection of coastal populations, economic development, and ecosystem integrity.

Nature-Based Coastal Defense: Where Are We?

The need for sustainable and cost-effective flood and storm mitigation for coastal human communities has renewed interest in coastal protection provided by natural ecosystems. A variety of coastal and riparian ecosystems, including dunes, mangroves, marshes, seagrass beds, and coral and shellfish reefs, are recognized for their provision of coastal protection (UNEP, 2006; MEA, 2005; Barbier *et al.*, 2008; Barbier *et al.*, 2011). These coastal ecosystems form physical structures that attenuate waves, decrease water velocities, block winds and reduce erosion, and therefore function in a similar way as human-made coastal defense structures such as levees and dams (Table 1).

Coastal ecosystems that attenuate waves diminish coastal flooding and increase shoreline stability (Gedan *et al.*, 2011;

Table 1 Listing ecosystems, their coastal defense properties, and additional services

<i>Ecosystem</i>	<i>Coastal defense properties</i>	<i>Additional services</i>
Coral reef	Wave dampening	Nature, tourism, food provisioning (fish)
Shellfish reef	Wave dampening	Nature, food provisioning (fish and shellfish)
Salt marsh	Wave dampening	Nature, nursery for seafood species
Riverine wetland	Flood defense, water retention	Nature, nursery
Dunes and sandy beaches	Flood defense	Tourism and recreation, water purification
Seagrasses	Mediation of currents and waves	Nature, nursery for fish, clam habitat
Mangroves	Reducing wave impact and current velocities	Nature, provisioning of food and firewood, tourism

Koch *et al.*, 2009; Borsje *et al.*, 2011). The physical structure of coral and shellfish reefs, salt marshes, and mangroves create friction (i.e., drag), which slows water velocities (Christiansen *et al.*, 2000; Mazda *et al.*, 1997) and attenuates waves (marsh Coops *et al.*, 1996; Moller *et al.*, 1999; Moller, 2006; mangrove Mazda *et al.*, 1997 protection; shellfish reefs Borsje *et al.*, 2011; coral reefs, Hardy and Young, 1996, Lugo-Fernandez *et al.*, 1998). Mangrove and marsh canopies and dunes block wind and reduce fetch and can further reduce wave heights (Campbell *et al.*, 2009). The structure created by organisms in these coastal ecosystems also reduces the erosion of bed sediments and helps to stabilize shorelines by reducing water velocities and turbulence (marsh, Neumeier and Ciavola, 2004; mangrove, Mazda *et al.*, 1997 drag; oyster reefs Piazza *et al.*, 2005). In addition, biotic structures such as roots, rhizomes, and shell debris provide a physical barrier between sediments and erosive water flow (mangrove, Mazda *et al.*, 2006).

A significant feature of all of these coastal ecosystems is that they are biogenic, or built over time by organisms. Modification of the coastal environment by shellfish, corals, sea grasses, dune plants, salt-marsh grasses, and mangroves bears indirectly on sediments and bathymetry in ways that reduce wave heights and shoreline erosion beyond the direct effects of drag reduction. Because wave heights are largely determined by water depth (le Hir *et al.*, 2000), mangrove and marsh plants that affect the elevation of intertidal surfaces by building peat platforms have strong indirect effects on wave heights (Fagherazzi *et al.*, 2006). Biogenic structures can accumulate over decades and centuries, accreting meters in elevation over the underlying substrate (marsh, Marani *et al.*, 2007; Kirwan and Murray, 2007). The sediment deposition facilitated by plants and animals can also affect the stability of the coastal system. In salt marshes, the decay of a dense root mass enriches soil organic content, which is associated with slower erosion than more mineral-rich wetland soils (Feagin *et al.*, 2009). Particles bound by mussels and oysters as pseudofaeces increase sediment cohesion and reduce erosion of intertidal flats (van Leeuwen *et al.*, 2010; Borsje *et al.*, 2011 and citations within).

Although, in general, the evidence that biogenic coastal habitats protect shorelines is overwhelming, we still lack important information for predicting when and where these services are effective and can be used for coastal engineering. One major knowledge gap is the scale at which shoreline protection services of different ecosystems are applicable. For example, changes in the shoreline across very large scales along the Thai coastline can be explained by the presence of mangrove forests (Thampanya *et al.*, 2006), whereas oyster reef

restorations (Scypher *et al.*, 2011) and salt-marsh vegetation (Feagin *et al.*, 2009) have failed to have a detectable effect on shoreline change at small spatial scales. There are several reasons these discrepancies occur and may impede the generalization and scaling up of shoreline-protection services.

Shoreline-protection services exhibit stark nonlinearities over space and time, due to variation in biotic structures over seasons or years (Figure 1, multiple habitats, Koch *et al.*, 2009; coral reefs, Wilkinson *et al.*, 1999; Sheppard *et al.*, 2005) and due to physical effects that are strongest at the habitat fringe (Kennedy and Mayer, 2002; Möller and Spencer, 2002; Gedan *et al.*, 2011). These nonlinearities have been considered more thoroughly for some coastal ecosystems – for example, seagrass beds (Koch *et al.*, 2009), mangrove forests (Barbier *et al.*, 2008), and marshes (Kennedy and Mayer, 2002; Möller and Spencer, 2002) – than for others. Still, no general rules of thumb have been derived that determine shifts of energy reduction by vegetation. This is mainly due to the lack of controlled measurements on realistic scales (Fonseca and Cahalan, 1992; Mendez and Losada, 2004).

Depending on the biological requirements of the dominant organisms, coastal ecosystems are constrained in their development and self-sustainability by environmental conditions such as elevation, currents, and wave exposure (Piazza *et al.*, 2005; Borsje *et al.*, 2011; Gedan *et al.*, 2011), and better definitions of these constraints are necessary to apply natural shoreline-protection services more broadly. In addition, climatic and tidal-stage conditions and storm track can have a large impact on the effectiveness of coastal ecosystems in shoreline protection (Resio and Westerink, 2008), making it difficult to predict the effectiveness of ecosystems for a given storm or flooding event until after the event occurs. Moreover, there are few scientific studies of wave attenuation or coastal protection during catastrophic wave events such as tsunamis, making it even more difficult to establish, with any level of certainty, the effectiveness of coastal ecosystems in protection from these events, which impedes inclusion of ecosystems in coastal-protection schemes. Nevertheless, damage analyses do often show protection of communities situated adjacent to coastal ecosystems from even these catastrophic events (Laso Bayas *et al.*, 2011; Danielson *et al.*, 2005; Das and Vincent, 2009).

Finally, as we present in this chapter, the roles of species identity and species composition in coastal-protection services have been insufficiently investigated. However, through mechanisms identified in studies of biodiversity and ecosystem function and of natural coastal protection, it is likely that mixtures of species and habitats can increase the effectiveness of natural shoreline-protection services.

Figure 1 Examples of nonlinearities in wave attenuation for a variety of habitats. Direct measurements of wave attenuation only exist for the smallest spatial (a; [Massel et al., 1999](#); [Möller, 2006](#)) and temporal (d; [Mazda et al., 2006](#); [Möller et al., 2006](#); [Chen et al., 2007](#)) scales. Wave attenuation for different mangrove densities (b) has been modeled ([Massel et al., 1999](#)). Latitudinal wave attenuation (c) is estimated, based on the aboveground biomass of mangroves ([Twilley et al., 1992](#)) and sea grasses ([Duarte and Chiscano, 1991](#)) – that is, obstructions to water flow. Wave attenuation over different seasons is also assumed to change with marsh aboveground biomass (e; [Morris and Haskin, 1990](#)). Interannual variability in coral (modified from [McClanahan et al., 2005](#)) and seagrass ([Merkel, 2008](#)) area cover (f) is used to estimate long-term trends in wave attenuation. Reprinted from Koch EW, Barbier EB, Silliman BR, et al. (2009) Nonlinearity in ecosystem services: Temporal and spatial variability in coastal protection. *Frontiers in Ecology and the Environment* 7: 29–37.

How Biodiversity Can and Does Matter on Different Scales

A range of ecosystem types contribute to coastal protection (e.g., oyster reefs, coral reefs, salt marshes), and although all these systems damp incoming physical stress from water and wind, the type of ecosystem present is likely to be an important determinant of the degree of coastal protection provided. For example, existing studies provisionally suggest that, although shellfish reefs and mangroves both contribute to wave

dampening and shoreline stabilization, mangroves are substantially more effective in both (*shellfish reefs*; Folkard and Gascoigne, 2009; *van Leeuwen et al., 2010*, *mangroves*; [Quartel et al., 2007](#); [Ellison, 2000](#)). Within ecosystem types, the efficacy of shoreline protection can also vary with the identity of species. For example, in controlled laboratory settings, differences in effectiveness of wave dampening and sediment trapping have been observed for single-species beds within both marsh plants and sea grasses ([Fonseca and Calahan, 1992](#); [Coops et al., 1996](#); [Peralta et al., 2008](#)). These observed differences

between species suggest that the identity of the dominant species may be an important determinant of the degree of coastal protection provisioned by a specific coastal ecosystem, which is consistent with a large body of experimental work examining the effects of biodiversity on ecosystem functions (reviewed by Hooper *et al.*, 2005). The identity of dominant species can change across time and space within any single coastal ecosystem type and should thus be considered in assessments and predictions of coastal-protection potential.

Drawing on theory and past experiments linking biodiversity and ecosystem function (e.g., Balvanera *et al.*, 2006), we predict that the ecosystem services of wave dampening and sediment trapping should be enhanced by species diversity (the number of species present), not simply vary as a function of species identity (i.e., a sampling effect). More precisely, although the elevation of these services with increased diversity could stem directly from the greater probability of including one or more exceptional species, it may also result from emergent effects of diversity per se, through the inclusion of species that inhabit complimentary niches. Although this hypothesis has yet to be explicitly tested for shoreline-protection services, there is evidence that combinations of different species on local scales can have greater impacts on hydrodynamics and sedimentation rates than any species in isolation (e.g., via differences in stoichiometry; Bouma *et al.*, 2005, 2010). Species also clearly show complementarity across space, especially in coastal ecosystems that are often characterized by steep physical gradients and marked zonation of species. It remains unclear how small-scale studies might scale up to explain patterns at larger spatial scales; however, we know from some systems that small-scale interactions can influence landscape patterns over larger scales (e.g., salt marshes; Temmerman *et al.*, 2007; Kirwan and Murray, 2007; van Wesenbeeck *et al.*, 2008).

Niche complementarity is likely to be most important, however, when multiple ecosystem functions or services are considered simultaneously (Gamfeldt *et al.*, 2008; Isbell *et al.*, 2011). This theory may well apply to shoreline protection, as this service involves multiple ecological effects – wave dampening, soil trapping, reduction of water velocity, accretion, and soil effects all contribute to shoreline protection – and even if certain species contribute more to one aspect of coastal protection (e.g., wave dampening by a rigid-bodied species), others contribute to another (e.g., soil stabilization by a soft-bodied species) and no single species (or group of similar species) is sufficient to sustain the multipronged service of coastal protection. For example, Ewel *et al.* (1998) speculate that fringe and riverine mangroves may be more effective at wave attenuation than basin mangrove forests, but basin mangrove forests may be more important for flood storage capacity.

At the landscape level, different kinds of coastal ecosystems have different functional roles in coastal defense, and so cross-ecosystem linkages may be very important for shoreline protection. For example, coral reefs have large implications for wave dampening by functioning as submerged breakwaters (Möller *et al.*, 1999; Kench and Brander, 2006), and mangroves are efficient sediment trappers, thereby stabilizing the shoreline (Ellison, 2000). Often these systems are found co-occurring along coastlines, as mangroves and marshes are generally restricted to low wave-energy environments (Knutson *et al.*, 1981; Ewel *et al.*, 1998), but the presence or placement of a reef

at the seaward margin may allow the wetland to persist in a more wave-exposed environment (Figure 2). It seems intuitive that waves are dampened more if they meet a shellfish reef and a mangrove forest than if they meet a mudflat and an eelgrass meadow due to the rigidity and the relative height of their biotic structures. However, surprisingly few data support this idea (see discussion in Barbier *et al.*, 2008). Thus, we are limited in our ability to predict if and to what extent different combinations of coastal communities can enhance or hinder coastal shoreline-protection services. Indeed, much additional research is needed in this area.

The extent to which these different coastal ecosystem types can influence coastal defense properties is dependent on having natural, functioning, and stable food webs within each. For example, salt marshes that have experienced significant grazing have distinct features (Bakker, 1981, 1985) that change their effects on wave attenuation. The lower-standing biomass of grazed marshes (Figure 3) can reduce wave-dampening

Figure 2 New restorations are pairing multiple habitat types for greater effectiveness in shoreline protection (B. Silliman). Reprinted from Gedan KB, Kirwan ML, Wolanski E, Barbier EB, and Silliman BR (2011) The present and future role of coastal wetland vegetation in protecting shorelines: Answering recent challenges to the paradigm. *Climatic Change* 106: 7–29, with permission from Springer.

Figure 3 Grazed marshes (front) differ considerably from ungrazed marsh systems (back). Evidence suggests that intensive grazing and trampling may have a negative effect on coastal defense properties. Photo published with permission from Martin Stock.

properties of marshes and intensive grazing was shown to reduce the strength of marsh soils (Zhang, 1993), which might make marshes more vulnerable to wave erosion. Further, food-web complexity and structure are also important because they influence ecosystem stability. For example, large diebacks of salt marshes in the southeast US have been linked to declines of a keystone predator, the blue crab (Silliman and Bertness, 2002). Reduction in blue crab numbers releases fungal-farming snails from predation allowing snail numbers to increase to levels high enough to graze down marsh grasses and transform the tidal marsh into mudflats (Silliman and Bertness, 2002). The ecosystem service of coastal protection offered by a healthy salt marsh is considerably greater than that offered by an intertidal mudflat. This example shows that food-web interactions are often complex and that understanding these interactions is crucial for successful implementation of nature-based coastal defenses. Further, it highlights the value of maintaining biotic diversity and food-web structure in ecosystems to maximize their effectiveness in providing coastal protection.

An advantage of natural shoreline protection over human-made coastal defenses is that natural shoreline protection is self-sustaining. Natural shorelines require less maintenance and can naturally adapt to changing environmental conditions such as rising sea levels over time. Therefore, applications of nature-based shoreline-protection strategies should also attempt to maximize ecosystem resilience. Maintaining greater species diversity is expected to maximize ecosystem output (Cardinale *et al.*, 2006) and increase ecosystem stability over time (Cottingham *et al.*, 2001; Griffin *et al.*, 2009b), and more diverse ecosystems are therefore likely to improve the provision of shoreline-protection services over the long term.

Shoreline protection by natural ecosystems represents an elegant compromise for achieving the goals of maintaining biodiversity and ecosystem integrity while also providing shoreline protection as well as many other benefits to human communities. Still, to improve applicability of nature-based flood defenses, more knowledge needs to be collected on design, maintenance, management, and governance. Preferably, this knowledge should be derived from real-scale applications that are accompanied by a thorough monitoring program. Conserving and promoting biodiversity in coastal ecosystems conserved or created for shoreline protection will help to maximize the myriad ecosystem services they provide, including benefits of fisheries and other natural resources, recreational activities, and water and nutrient regulation.

Conclusions

Awareness is rising that functioning, intact coastal ecosystems offer valuable coastal-protection services. By implementing ecosystem management in planning designs for coastal defenses, we can make use of the unique organisms that have evolved in and are well adapted to shoreline stressors. This requires an integrated planning and design process and a solid understanding of natural processes and ecosystem functioning. Making use of general ecological theory is

indispensable for adequate restoration and conservation of ecosystems in general.

The effectiveness of coastal ecosystems for wave dampening, reducing current velocities, slowing erosion, and facilitating biotic diversity depends on the types of coastal communities that are present (e.g., oyster reef, coral reef, mangrove, etc.) and on the spatial configuration of these communities.

Degenerated ecosystems that lack natural species assemblages are not likely to be as robust, stable, and resilient as intact ecosystems and therefore are less likely to provide the valuable ecosystem services that many coastal communities depend on. In general, higher diversity is thought to increase ecosystem stability, enhance resilience to perturbations, and increase productivity. Therefore, managing coastal ecosystems to promote diverse and natural species assemblages will enhance the effectiveness of these systems as protection. However, the exact implications for management and conservation depend on whether species-specific effects and possible positive interactions are well understood; if they are, then managing for particular species in order to maximize the yield of certain services may be more efficient than managing for diversity *per se*.

There is a need for large-scale experiments and replicated comparative studies to test how diversity within different levels of ecological organization (species, genetic and ecosystem) impacts coastal shoreline protection. We cannot advance our understanding of biodiversity–ecosystem service relationships unless proper controls are utilized when assessing impacts of proposed nature-based coastal-protection plans.

Incorporating the construction and maintenance of functional coastal ecosystems as a part of coastal defense strategies will require greater collaboration between ecologists, geologists, and engineers. It will also require focused research efforts aimed at documenting and quantifying the flood-defense properties of ecosystems. Such data are needed to develop predictive models that will allow coastal managers to assess the level of protection provided by specific coastal ecosystem configurations and therefore also estimate the potential socioeconomic impacts of ecosystem loss.

Glossary

Acidification The process by which soil pH is reduced, potentially causing release of toxic minerals into the soil, base cation depletion, losses of plant biodiversity, and dominance by acid-tolerant species.

Calcareous A soil property of high calcium carbonate (CaCO_3) which buffers the soil against changes in pH.

Critical Load A quantitative estimate of an exposure to a pollutant below which significant harmful effects on specified elements of the environment do not occur according to present knowledge.

Denitrification A biogeochemical process mediated by soil microbes in which nitrate (NO_3^-) is converted to dinitrogen gas (N_2) along with other intermediary molecules.

Eutrophication The process by which enrichment with nutrients such as nitrogen stimulates plant growth, often

leading to losses of plant biodiversity and dominance by weedy species.

Limiting resource The resource that most limits primary production in ecosystems (often nitrogen).

Nitrification A biogeochemical process mediated by soil microbes in which ammonium (NH_4^+) is converted to nitrate (NO_3^-) along with the release of protons into the soil.

Nitrogen deposition The process by which reactive forms of nitrogen are deposited to the earth's surface through either wet or dry deposition.

Reactive nitrogen All forms of nitrogen except atmospheric dinitrogen gas, includes all radiatively, photochemically, and biologically active inorganic forms (e.g., NH_3 , NH_4^+ , NO_x , HNO_3 , N_2O) and organic molecules (e.g., proteins, urea, etc.).

Overview of the Issue

Nitrogen deposition, along with habitat losses and climate change, has been identified as a primary threat to biodiversity worldwide (Butchart *et al.*, 2010; MEA, 2005; Sala *et al.*, 2000). The source of this stressor to natural systems is generally two-fold: burning of fossil fuels and the use of fertilizers in modern intensive agriculture. Each of these human enterprises leads to the release of large amounts of biologically reactive nitrogen (henceforth contracted to “nitrogen”) to the atmosphere, which is later deposited to ecosystems. Because nitrogen is a critical element to all living things (as a primary building block of proteins among other biological molecules), nitrogen availability often limits primary production and is tightly recycled in many natural ecosystems. This is especially true in temperate ecosystems, though it may also be true for some areas in the tropics that are not phosphorus-limited (Adams *et al.*, 2004; Matson *et al.*, 1999). Thus, the large increase in availability of this critical nutrient as a result of human activity has profound impacts on ecosystems and on biodiversity.

Once nitrogen is deposited on terrestrial ecosystems, a cascade of effects can occur that often leads to overall declines in biodiversity (Bobbink *et al.*, 2010; Galloway *et al.*, 2003). For plants, nitrogen deposition can impact biodiversity generally through four processes: (1) stimulation of growth often of weedy species that outcompete local neighbors (termed “eutrophication”), (2) acidification of the soil and consequent imbalances in other key nutrients that favors acid tolerant species (termed “acidification”), (3) enhancement of secondary stressors such as from fire, drought, frost, or pests triggered by increased nitrogen availability (termed “secondary stressors”), and (4) direct damage to leaves (termed “direct toxicity”) (Bobbink, 1998; Bobbink *et al.*, 2010). For animals, much less is known, but reductions in plant biodiversity can lead to reductions in diversity of invertebrate and other animal species, loss of habitat heterogeneity and specialist habitats, increased pest populations and activity, and changes in soil microbial communities (McKinney and Lockwood, 1999; Throop and Lerdau, 2004; Treseder, 2004).

In total, it is estimated that nearly 16.3 million km² or 11% of the terrestrial land surface is currently exposed to high levels of nitrogen deposition that could threaten biodiversity (Dentener *et al.*, 2006). Regions vary globally in the amount of area exposed, ranging from eastern Europe (80%), to South Asia (60%), east Asia (40%), southeast Asia (30%), western Europe (30%), and the US (20%), with the remaining global regions being generally low (<10%). Thus, nitrogen deposition potentially impacts biodiversity over much of the globe, from tropics to tundra. Although the biodiversity of most systems responds negatively to nitrogen deposition, the magnitude and exact nature of the effect can vary widely depending on interactions between nutrient availability and other factors such as climate, disturbance, and plant community composition (Bobbink *et al.*, 2010; Dise, 2011).

It is unclear to what degree recovery of biodiversity is possible from long-term nitrogen deposition. Recovery is anticipated to be enhanced through reduction of soil nitrogen availability, restoration of soil pH and other nutrient conditions, and addition of species formerly lost (Bakker and Berendse, 1999). In practice, it is unresolved to what degree this process occurs naturally if nitrogen deposition were reduced through regional, national, or international regulation. However, over time periods of interest to decision makers (years to decades) active management may be necessary to restore biodiversity within affected areas (Dise, 2011).

Many of the world's "hot spots" of biodiversity are either currently exposed, or are expected to be exposed in the near future, to potentially high levels of nitrogen deposition as industrialization continues to occur in developing nations of the Tropics and Asia (Phoenix *et al.*, 2006). Most of our knowledge on the impacts from nitrogen deposition comes from Europe and the US – areas that have already experienced modern industrialization and widespread losses of biodiversity – and, using short-term experiments in which high levels of N in excess of deposition were added. Thus, there is an urgent need for a greater understanding of the long-term impacts from low levels of nitrogen deposition in all systems, with particular emphasis on understudied biomes and geographic areas such as the Tropics, Asia, and Africa (Bobbink *et al.*, 2010).

Background on Nitrogen as a Nutrient and Pollutant in Ecosystems

Nitrogen as a Nutrient and Resource Limitation

Nearly 99% of the nitrogen (N) on the planet is in the atmosphere as highly stable dinitrogen gas (N₂), where two atoms of N are triple-bonded together. N is the most abundant element in our atmosphere, making up approximately 78% by volume, followed by oxygen (~20%) and Argon (~1%) (Galloway *et al.*, 2003). N is also one of the most critical elements for life, constituting the elemental basis for peptide bonds between amino acids, which combine to form proteins – the basic building blocks for the biochemical reactions underpinning all life.

Figure 1 Illustration of biological nitrogen fixation (BNF). Clockwise from the top: Simplified chemical equation of BNF; some common N fixing plants, soybean, lupine, alder; and a closeup of plant roots and the root nodules where BNF takes place for leguminous species.

Ironically, however, atmospheric nitrogen is unavailable to approximately 99% of living organisms (Galloway *et al.*, 2003). The ability to break this triple bond, thereby converting N₂ into more reactive forms, is relatively rare in nature. It requires significant energy, low oxygen levels, specialized enzymes, and is almost entirely the purview of bacteria and archaea (the group capable termed diazotrophs). These organisms generally live either freely in the soil or in water, or in close association with plant roots belowground, and are responsible for this biological nitrogen fixation (BNF, Figure 1). Lightning can also break the triple bond of N₂, though the importance of lightning to global N supplies is small by comparison to BNF. Thus, N₂ is commonly termed "non-reactive N" because it is inert to all but a small fraction of organisms. The remaining 1% of planetary N includes all biologically, photochemically, and radiatively active compounds in the atmosphere, hydrosphere, geosphere, and biosphere (termed "reactive N" or "Nr"). Nr includes dozens of different molecular forms, including inorganic oxidized N (e.g., nitric acid (HNO₃), nitrogen oxides (NO_x), nitrous oxide (N₂O), and nitrate (NO₃⁻)), inorganic reduced N (e.g., ammonium (NH₄⁺) and ammonia (NH₃)), and organic N (e.g., proteins, urea, or amines) (Galloway *et al.*, 2003).

The importance of nitrogen to all biological functioning, and its relatively restricted supplies, means that its availability often limits primary production in natural ecosystems (Vitousek *et al.*, 2002). Other nutrients can also limit production, especially phosphorus, though nitrogen limitation or colimitation is widespread in terrestrial ecosystems (Elser *et al.*, 2007; LeBauer and Treseder, 2008). Because the ultimate source of phosphorus is chemical weathering of mineral rocks, older systems that have not been glaciated for millennia can develop P limitation, a condition often observed in tropical regions (Matson *et al.*, 1999). Nonetheless, nitrogen limitation is also observed in many tropical areas.

Figure 2 The global nitrogen cycle showing approximate magnitudes of major pools (boxes) and fluxes (arrows) in teragrams per year ($1\text{Tg}=10^{12}\text{g}$). The atmosphere contains the vast majority of Earth's nitrogen, followed by oceanic rocks and sediments and the soil. The amount of N that cycles in terrestrial and marine systems is much greater than N inputs from BNF (nine-fold and 80-fold respectively). Reproduced with permission from Chapin FS, Matson PA, and Mooney HA (2002) *Principles of Terrestrial Ecosystem Ecology*. New York: Springer-Verlag.

Nitrogen Cycling: Preindustrial and Postindustrial

Prior to the industrial revolution, creation of N_r came from three sources: BNF, lightning, and preindustrial agriculture. Together, these processes added N_r to terrestrial ecosystems at roughly 141 TgN/year ($\text{Tg}=10^{12}\text{g}$), which was predominantly natural BNF (BNF: 92%; preindustrial agriculture: 6%; lightning: 2%; Galloway *et al.*, 2004). There was some anthropogenic-driven BNF through the cultivation of rice paddies, but this was small by comparison. Most of these nitrogen inputs were transferred to the ocean, denitrified to the atmosphere, or accumulated slowly as organic material in soils. All these processes are part of the global nitrogen cycle (Figure 2).

Human activity began to substantially impact the global nitrogen cycle following the industrial revolution from the burning of fossil fuels for energy and the advent of modern agriculture. When fossil fuels are burned at high temperatures in the presence of atmospheric oxygen, many oxidized forms of N_r are produced (e.g., nitrogen oxides such as NO_x). These

molecular forms of N_r disperse and react with the atmospheric constituents, eventually being deposited through either wet or dry nitrogen deposition.

The advent of modern agriculture also had a major impact on the global nitrogen cycle (Smil, 2001). In the late nineteenth and early twentieth centuries, nitrogen for fertilizer and explosives came mainly from nitrate salts mined in the Atacama desert of Chile and from animal droppings on islands off the coasts of Chile and Peru. There was a global shortage developing for these resources, provoking a search for substitutes. Soon thereafter, German scientists Fritz Haber and Carl Bosch invented a process for synthesizing NH_3 from N_2 using high temperature, pressure, catalysts, and an abundant hydrogen source. This abundant and affordable N_r source was a major driver for increases in global food supply as a primary constituent of fertilizer. Some fertilizer N volatilizes into the atmosphere, leading to wet or dry deposition of reduced N to terrestrial ecosystems, though much of it leaches to aquatic ecosystems. Vitousek (1997) estimated that sometime in

Figure 3 Increases through time in anthropogenic N fixation from planting of leguminous crops, fossil fuel combustion, and fertilizer, as compared with all natural processes combined. Reproduced with permission from Galloway JN, Schlesinger WH, Levy H III, Michaels A, and Schnoor JL (1995) Nitrogen fixation: anthropogenic enhancement-environmental response. *Global Biogeochemical Cycles* 9: 235–252.

the past few decades, human additions to the nitrogen cycle exceeded all natural processes combined (Figure 3). A budget of the nitrogen cycle in 1890 (Figure 4(a)) and 1990 (Figure 4(b)) highlights the magnitude of these effects.

Nitrogen deposition is expected to continue to increase as developing nations industrialize (Figure 5). Because most terrestrial ecosystems developed under conditions of nitrogen scarcity, enriching global ecosystems with N_r can have dramatic effects.

Biodiversity and Nitrogen Deposition

Here the authors define biodiversity or biological diversity simply as the diversity of life within a particular system, including genes, species, communities, and ecosystems. Most research on nitrogen deposition has focused on the number of species within a particular area, termed species richness. The authors focus largely on impacts to plants, also because this is where most research focuses, and note that impacts on other trophic levels often stem from the impacts on the plant community. Some impacts that occur on other trophic levels are elaborated below.

How Nitrogen Deposition Impacts Terrestrial Biodiversity

Nitrogen deposition, after habitat losses and climate change, is considered the major threat to biodiversity worldwide, with increasing stresses on some of Earth's most diverse areas (Figure 6, Table 1). For plants, N deposition affects terrestrial biodiversity through four primary mechanisms: (1) eutrophication, (2) acidification, (3) exacerbation of secondary stress, and (4) direct toxicity (Figure 7). These mechanisms will not operate – or have equal importance – in all ecosystems. The strength of each of these four mechanisms are influenced by other modifying factors discussed in Characteristics Describing Sensitivity to Nitrogen Deposition. Impacts on animals are less well studied, and are presented in

the taxa-specific subsections of the Section Conditions that Alter the Magnitude of Impacts on Biodiversity (e.g., for soil biota, insects, mammals, etc.). Here the authors describe these mechanisms affecting plants and their properties generally.

Eutrophication

Eutrophication describes the process of N loading increasing availability of N in the soil to plants, which often leads to a cascade of effects. Because plant growth in many ecosystems is limited by the availability of nitrogen (Elser *et al.*, 2007), this is a direct process where concentrations increase in the soil and plant growth increases. Over time, a positive feedback can emerge, where increases in plant tissue N stimulates further increases in decomposition and liberation of more N. Overall, this increase in N availability often stimulates the growth of fast-growing species (termed “nitrophilous” species), resulting in competitive exclusion of less responsive species. Species that are rare, slow growing, and native are often lost more than other species, though this is not always the case (Suding *et al.*, 2005). Because most species are adapted to low nutrient availability (the prevailing condition), they are less responsive than weedy species, and are outcompeted through competition either for light aboveground and/or nutrients belowground. Eutrophication may result in expansion of aggressive species already in the plant community, or facilitate invasion by species not originally present. Eventually, ecosystems become saturated with N, and their productivity becomes limiting by other factors such as water or P. Even so, tissue concentrations of N may further increase, leading to potential nutrient imbalances, physiological stresses, and/or increased losses to herbivory (Dise, 2011).

Acidification

Acidification describes the process by which addition of N decreases soil pH, which can have a variety of direct and indirect effects on plant growth. Generally during acidification, changes in soil pH are mitigated by the release of carbonates and base cations from the soil (Bowman *et al.*, 2008). Once these are exhausted, clay minerals in the soil can breakdown leading to the release of toxic minerals into the soil (especially aluminum, Al³⁺). N deposition can result in acidification through a number of mechanisms, including (1) stimulation of nitrification which yields protons (H⁺), (2) roots uptake of NH₄⁺ releasing H⁺ as a counter ion, and (3) binding of NO₃[−] with base cations and subsequent loss via leaching (reduces soil buffering capacity) (Dise, 2011; Ulrich, 1983). Over long time periods, acidification can suppress nitrification and plant uptake of nitrogen, leading to further accumulation of acidifying compounds such as NH₄⁺ and a buildup of undecomposed material (Roelofs *et al.*, 1985). Acidification generally reduces biodiversity because there are fewer plant species adapted to more acidic soils, through suppression of germination, and through changes in the concentrations of either toxic minerals (e.g., Al³⁺) or nutrients (e.g., N, P, base cations) in the soil (Horswill *et al.*, 2008; Stevens *et al.*, 2010a).

Figure 4 Global nitrogen budget for (a) 1890, and (b) 1990 Tg N per year. Down arrows represent inputs to terrestrial and aquatic systems, up arrows represent inputs to the atmosphere, lateral arrows represent transfers (two shown: Via rivers from terrestrial to coastal marine systems, or via lightning). Systems and subsystems are (from left to right): open ocean, terrestrial (land burning, fossil fuel combustion, natural ecosystems, fertilizer production (absent in 1890), crop agriculture, and animal husbandry), and coastal marine systems. Arrow sizes are relative to flux rates. The emissions to the ' NO_y box' from the 'coal' reflect fossil-fuel combustion. Those from the 'vegetation' include agricultural and natural soil emissions, and combustion of biofuel, biomass (savannah and forests) and agricultural waste. The emissions to the ' NH_x box' from the 'agricultural field' include emissions from agricultural land and combustion of biofuel, biomass (savannah and forests) and agricultural waste. The NH_x emissions from the 'cow' and 'feedlot' reflect emissions from animal waste. Reproduced from Galloway JN and Cowling EB (2002) Reactive nitrogen and the world: 200 years of change. *Ambio* 31: 64–71, with permission from Royal Swedish Academy of Sciences.

Secondary Abiotic and Biotic Stressors

Secondary stresses may also be exacerbated by N deposition. For instance, increased winter injury and summer drought damage has been observed on *Calluna vulgaris* in heathland and bog ecosystems (Britton and Fisher, 2007; Sheppard *et al.*, 2008). The same species has shown increase infection from *Botrytis* and *Phytophthora* pathogens under enhanced N deposition (Sheppard *et al.*, 2008). The mechanisms causing winter, drought, and pathogen damage remain unclear, though greater stress sensitivity of more luxuriant growth, reduced biomass allocation to roots, lower mycorrhizal infection, shifts toward more parasitic associations belowground, and loss of essential nutrient ions such as Ca^{2+} have all been implicated (Bobbink *et al.*, 2010). N deposition has also been shown to lead to greater damage from invertebrate herbivores, which appears to be driven by greater foliar nutrient quality, reduced secondary defense compounds, and in some cases, greater

invertebrate herbivore growth rates when feeding on nitrogen enriched foliage (Power *et al.*, 1998; Throop and Lerdau, 2004).

Direct Foliar Damage

Although direct foliar toxicity is not generally assumed to be a prominent driver of biodiversity changes, impacts can occur when atmospheric N compounds are found at high concentrations, usually close to emissions sources, and for especially sensitive taxa that lack protective tissues and structures such as moss and lichens (Bobbink *et al.*, 2010). For higher plants, outer tissues are relatively impervious (e.g., cuticle layers of leaves) to Nr (e.g., NH_3), with impacts occurring following direct entry through the stomata (Krupa, 2003). Following entry, NH_3 can have a variety of effects on all plant types including inducing stomatal opening, nutrient imbalances, and disruption of cell membrane integrity, in addition to the

secondary stresses highlighted above following N assimilation into plant tissue (Krupa, 2003).

Research Approaches: How Do We Know What We Know?

Research efforts investigating ecological impacts associated with chronically elevated N deposition began decades earlier in Europe than in the rest of the world, in part because these problems arose earlier and were relatively more widespread. Most of the research on effects of excess N on terrestrial ecosystems has focused on biogeochemical responses, with far less research on effects on biodiversity. Studies examining biodiversity are heavily skewed toward plants. Even so, experimental studies examining the effects of N on species diversity of plant communities have a long history, with the first being the Park Grass Experiment in Rothamsted, England, established in 1858 (Silvertown *et al.*, 2006). More recent studies around the world find similar results of this earlier work – experimentally-added N profoundly alters species composition often decreasing species diversity of plant communities. In

terms of which ecosystems and regions are studied, most research has been carried out on herb-dominated communities in temperate areas, and far fewer have been done in forested ecosystems and in the tropics (Bobbink *et al.*, 2010; Gilliam, 2007). These are significant discrepancies, considering that temperate forests often occupy areas receiving high rates of atmospheric deposition of N, and many tropical areas are expected to experience increased N deposition as development intensifies in the coming decades (Phoenix *et al.*, 2006).

Research approaches toward determining the response of plant biodiversity to increasing N deposition can be divided into three broad categories: observational studies, manipulative studies, and modeling. Observational studies are divided into two types, often termed “gradient” and “resampling” studies. Gradient studies examine biodiversity patterns across N deposition gradient(s) from areas of low to high N deposition. Resampling studies measure biodiversity at a particular location, comparing patterns when N deposition was low (usually in the past) with patterns when N deposition is/was high (usually current). Manipulative, or experimental, approaches involve controlled addition of N in various forms and amounts to plots or watersheds (much more rare) and measuring the

biodiversity response. Integrated soil-vegetation models show much promise in integrating our combined understanding of the process of N induced changes in biodiversity, though significant challenges exist. Most modeling approaches combine two modeling phases: (1) examination of the impacts of N deposition on soil solution N, water, and soil pH, and (2) the impacts of these changes on plant community structure (*De Vries et al.*, 2010). Models differ in many substantial ways, including the use of statistical relationships to derive results, the degree of resolution for ecological processes, the input parameters and variables computed (*De Vries et al.*, 2010).

Each of these approaches has strengths and weaknesses with respect to each other, which are often exclusive (Table 2). As reviewed by *Gilliam* (2006), modeling studies are much less prevalent than empirical work, with observational studies tending to be more common in Europe, and manipulative studies are generally more common in North America, South America, and Asia.

Conditions that Alter the Magnitude of Impacts on Biodiversity

Ecosystem-specific Effects of Nitrogen Deposition on Biodiversity

The effects of N deposition on ecosystems worldwide can depend on a variety of abiotic and biotic factors, including climatic factors, soil properties, preexisting nutrient limitations,

productivity, and history of N deposition (see *Bobbink et al.*, 2010 for a comprehensive review). In many ecosystems including deserts, temperate grasslands, savannas, shrublands, and Mediterranean systems, N enrichment can lead to increases in nonnative grasses, at the expense of native forb abundance and diversity. Many times this leads to an overall decrease in biodiversity (*Bai et al.*, 2010; *Clark and Tilman*, 2008, *Allen et al.*, 2009, *Zavaleta et al.*, 2003). Generally speaking, temperate ecosystems appear more sensitive to N-induced species declines than tropical systems because the former are more N-poor (as opposed to the more P-poor tropics) (*Matson et al.*, 1999). Arctic systems may be particularly sensitive for similar reasons, though low deposition rates in these areas and short growing seasons may limit responses in these ecosystems. Responses in montane systems such as high alpine meadows may be similarly limited, although orographic lifting of air masses leads to disproportionately high levels of N deposition compared with lowlands below (*Weathers et al.*, 2006). The effects of N deposition on acid soils such as those found in Europe is predominantly due to soil acidification, whereas in well-buffered calcareous soils the major mechanism is eutrophication. Finally, wetter systems appear more sensitive than drier systems within a biogeographic region because the latter are more likely to be colimited by water and therefore less responsive to added N (*Clark et al.*, 2007).

These generalities above, however, belie complex responses that can occur for any of these ecosystems and regions.

Table 2 A survey of the major approaches to studying the impacts of nitrogen deposition on biodiversity

Type of study	Brief description	Strengths	Weaknesses	Examples (Figure 8)
Observational-gradient	Measure biodiversity across a transect from high to low nitrogen deposition at one point in time	● Realistic nitrogen deposition profile (amount, form, timing, etc.) ● Large scale represents dispersal limitations	● Other factors change along the gradient that may explain the biodiversity pattern (e.g., soil, land-use, climate, plant community) ● More difficult to detect pattern because of low signal to noise ratio	Maskell <i>et al.</i> (2010), Stevens <i>et al.</i> (2004, 2010b)
Observational-resampling	Measure biodiversity at one location comparing when deposition was low (e.g., the past) with when deposition is high (e.g., current)	● Realistic nitrogen deposition profile (amount, form, timing).	● Other factors that change through time may explain the biodiversity pattern (e.g., land-use, climate) ● More difficult to detect pattern because of low signal to noise ratio	Bennie <i>et al.</i> (2006), Dupre <i>et al.</i> (2010), Smart <i>et al.</i> (2005)
Manipulative	Add controlled amounts of N to plots or watersheds and measure biodiversity response	● Greater isolation of the effect of N, fewer confounding factors ● Replication allows for greater statistical strength and higher signal:noise ● If watersheds are the experimental unit, large scale realistically represents deposition	● Treatments often do not accurately represent deposition (one time addition of often large amounts of N in solid granular form) ● Usually replicate plots are small (e.g., from 10 m × 10 m to 1 m × 1 m); or, large watersheds are unreplicated	Bowman <i>et al.</i> (2006), Clark and Tilman (2008) Gilliam (2006), Morecroft <i>et al.</i> (1994), Suding <i>et al.</i> (2005)
Modeling	Process and/or statistical models relating deposition to biodiversity	● Captures the full dynamics of how nitrogen impacts biodiversity through eutrophication and acidification pathways	● Based on current, often incomplete knowledge ● Large data input requirements that are often lacking ● Secondary factors and direct toxicity not currently modeled	Belyazid <i>et al.</i> (2011), De Vries <i>et al.</i> (2010), Sverdrup <i>et al.</i> (2007)

For example, although deserts as a whole may be less responsive than nondeserts, deserts in southern California have been invaded by fast-growing grasses are very responsive. This leads to a strong reduction in diversity and increases risk of fire that may additionally impact diversity (Rao *et al.*, 2010). In addition, some European heathlands may show little changes in diversity initially. But, following increases in plant N over years of N enrichment, pest outbreaks can lead to increased light levels at the soil and rapid changes in biodiversity including increased grass dominance (Strengbom *et al.*, 2002; Bobbink *et al.*, 2010). In summary, although there is a wide range of potential responses to N deposition, terrestrial biodiversity in most systems is negatively affected through one or more mechanisms.

Taxa Specific Responses to Nitrogen Deposition

Nonvascular Plants

In general, nonvascular plants are the most sensitive to nitrogen enrichment, followed by herbaceous plants and shrubs, with trees being the least sensitive. The unique anatomy of nonvascular plants (e.g., lichens, bryophytes, liverworts, and mosses) makes them highly sensitive to fluctuations in atmospheric sources of N. Nonvascular plants lack root structures to access

soil nutrient pools, and instead rely on nutrients directly absorbed from deposition, throughfall, and leachates from overstory vegetation. Their lack of a cuticle and vascular structures allows the passive, rapid absorption of water over their entire surface. Thus, they are particularly sensitive to deposited N. These inherent sensitivities causes nonvascular plants to respond to extremely low deposition levels, for instance, <3 kg N ha⁻¹ per year for epiphytic lichens in the Sierra Nevada, CA (Fenn *et al.*, 2008). Degradation of these nonvascular species communities has far-ranging consequences that are often overlooked because of their supposed diminutive role in ecosystem function. For example, *Sphagnum* bogs are major carbon sinks in temperate areas, reindeer lichen are critical forage for these ungulates during the winter months, and many lichen species are used by birds for nesting material.

Herbaceous Plants

Because herbaceous plants and shrubs have vascular systems and protective epidermal layers, they access most of their nitrogen through the soil and are not as sensitive as nonvascular species to high concentrations of nitrogenous compounds in the air. Once deposited, however, large impacts can occur because of their shallow root systems, short life spans, and rapid growth rates compared with forest trees. Some plants

Figure 8 Example studies of N deposition effects on plant biodiversity from observational spatial gradients in Europe (a, b: Reproduced from Stevens CJ, *et al.* (2010b) Nitrogen deposition threatens species richness of grasslands across Europe. *Environmental Pollution* 158: 2940–2945.), temporal resampling of British chalk grasslands in the 1950s compared with 2000s (c, d: Reproduced from Bennie J, Hill MO, Baxter R, and Huntley B (2006) Influence of slope and aspect on long-term vegetation change in British chalk grasslands. *Journal of Ecology* 94: 355–368, with permission from Wiley.), and experimental manipulations (e, f: Reproduced with permission from Clark CM and Tilman D (2008) Loss of plant species after chronic low-level nitrogen deposition to prairie grasslands. *Nature* 451: 712–715.). Total species richness (b) declined with total inorganic N deposition. In (b) there was an exponential decline in species richness with N deposition. From the 1950s to 2000s (c), there was a shift in the community composition toward nitrophilic species as estimated using statistically distinct axes of composition. In (f) total species richness declined through time at different rates from annual additions of fertilizer N to experimental plots.

respond negatively to N deposition, declining in occurrence and/or abundance when N inputs are high, others show positive responses benefiting from the additional N through direct or indirect mechanisms. In many temperate grasslands, savannahs, and shrublands, grasses become more dominant whereas the cover and biodiversity of forbs and other species declines. Some species are particularly sensitive, such as slow growing long-lived species that historically dominated much of the US great plains, and/or acid-sensitive species from heathlands and acid grasslands of Europe. In forests, herbaceous species (e.g., the understory) have a disproportionate significance to the biome compared with their abundance (Gilliam, 2007). Indeed, although they only represent ~0.2% of aboveground biomass, herbaceous understory species make up 90% of plant biodiversity and produce > 15% of the litter biomass. Thus, their losses may have large effects on many species that depend on them for forage and habitat.

Trees

Trees have long life spans, deep roots, and lower growth rates, characteristics that make them less susceptible to rapid changes in composition from N deposition. Nonetheless, shifts in relative growth rates among species within the community (stemming from rapid changes in N availability with N deposition) may portend to large biodiversity effects in the future (Bobbink *et al.*, 2010; Pardo *et al.*, in press; Thomas *et al.*, 2010). A seminal study by Thomas (2010) documented changes in forest tree growth rates with N deposition over much of the northeastern US, reporting that growth of many coniferous species declined whereas growth of tree species with arbuscular mycorrhizae increased, suggesting a strong potential for large-scale changes in forest composition. These patterns likely occurred because coniferous species are generally slower growing than broadleaf or deciduous species, and because trees with arbuscular mycorrhizae are better able to capitalize on deposited N (because these fungi can produce enzymes to break down N sources), whereas trees with other fungal associations such as ectomycorrhizal fungi cannot. Negative impacts from N enrichment in a tropical forest were found on a nutrient-poor acidic soil that was dominated by fast-growing pioneer species, all conditions leading to higher sensitivity (Siddique *et al.*, 2010).

Soil Microbes

Soil biota are capable of rapid changes in growth due to their small sizes and intimate association with soil particles and plant roots. They perform or aid in many critical ecosystem functions such as decomposition and nutrient uptake of N and P. Across various ecosystems, research has shown mixed effects on soil biotic communities, with some taxa increasing in abundance and diversity and others decreasing with N enrichment. However, for mycorrhizal fungi, many studies demonstrate a decline in reproductive output of species adapted to N-poor environments and their subsequent loss (Pardo *et al.*, in press). This is often associated with an increase in parasitic fungal species, declines in microbial diversity, and/or shifts in the soil community toward more bacterial dominance (Pardo *et al.*, in press). These patterns may be especially prevalent in systems with P-rich soils (Johnson *et al.*, 2003).

Unfortunately, given the need for additional study, few generalizations can be made about the response of soil biota.

Other Organisms

Higher trophic levels (hereafter consumers, including herbivores, carnivores, pests, etc.) are primarily affected indirectly by nitrogen deposition via nitrogen-induced changes in food quality or quantity (Throop and Lerdau, 2004). N concentration of plant tissue often increases with nitrogen enrichment, which can strongly, and typically positively, influence the individual performance, feeding behavior, and population dynamics of herbivores. Individual-level responses of insect herbivores can drive population-level increases and increased herbivory may in turn suppress positive impacts of N on plant biomass (Bertness *et al.*, 2008). These changes can subsequently alter ecosystem-level patterns of carbon and nitrogen cycling (Throop *et al.*, 2004). However, reductions in plant diversity and habitat homogenization has been found to reduce diversity of insects (Haddad *et al.*, 2000), which may extend to other trophic levels. Many responses of insect herbivores to N deposition are species-specific, and differential responses to N deposition can affect community composition of herbivorous insects. Considerably, less is known about the responses to N deposition on noninsect consumers. However, as highlighted in the European heathlands, elevated N has been associated with increased fungal pests (Nordin *et al.*, 2005; Pardo *et al.*, in press). Little work to date has documented whether N deposition effects on insect herbivores extend to higher-level consumers in field situations, although changes in prey quality from N additions may affect predator feeding behavior (Throop and Lerdau, 2004).

Overview on Vulnerability

The vulnerability of biodiversity to nitrogen deposition has two components: exposure and sensitivity. Exposure describes the amount, duration, form, and mechanism of nitrogen deposition. The sensitivity of the system describes the intrinsic properties of the ecosystem that may preclude a larger or smaller impact for a given amount of the stressor. Generally, this is described by properties related to abiotic and biotic characteristics of the community.

Characteristics Describing Exposure to Nitrogen Deposition

The exposure characteristics of nitrogen deposition can generally be described by the amount (rate), duration, timing, chemical form, and mechanism of deposition. These characteristics, in turn, are affected by regional land use practices (e.g., agricultural vs urban), industrial activities, climate, and orographic effects among others. A large number of experimental N additions and surveys have found a “dose-dependent” response to N deposition (e.g., Stevens *et al.*, 2004), with larger effects at higher rates of nitrogen addition. The more nitrogen is added, the greater the total effect. Timing of inputs also matters, where a greater effect might be expected if nitrogen is deposited during periods of active plant growth such as the spring and summer.

The chemical form of N deposition can also be an important determinant of impact. Differences have been observed in the impact of reduced and oxidized deposition (NH_x and NO_y) (summarized in Stevens *et al.* (2011)). Some plants have clear preferences for different N forms, and the form of N taken up by a plant may affect its health and performance. Also, the mechanism of deposition, whether deposited as wet deposition in rain, snow, or fog, on the leaf or soil surface, or as dry deposition onto leaf surfaces or the soil, may influence the impact of nitrogen deposition (Dise, 2011).

Characteristics Describing Sensitivity to Nitrogen Deposition

Abiotic Factors Affecting Sensitivity

Many abiotic factors influence the effect of a given amount of N on terrestrial biodiversity. The relative importance of each of these factors depends on which of the four dominant mechanisms (Figure 7) is driving changes in biodiversity. For systems in which eutrophication and competitive exclusion is the dominant mechanism, abiotic factors include the presence and strength of nitrogen limitation, the availability of open spaces for invasion by new species or expansion by existing species, and the availability and timing of other potentially limiting resources. For example, drier systems in the western US prairie tend to respond more weakly than wetter systems in the eastern plains (Clark *et al.*, 2007). Presumably, this occurs because the western plains are strongly colimited by nitrogen and water, whereas the eastern plains are primarily limited by nitrogen and therefore are better able to respond after N increases. Deserts have also been found to be less sensitive to N induced species declines in some but not all cases.

For systems in which acidification dominates, abiotic factors include soil pH, soil buffering capacity, weathering rates, as well as the availability and mobility of nutrient cations and toxic minerals in the soil. For example, systems with an already low pH and a low soil buffering capacity, might be more vulnerable to a given amount of nitrogen deposition than a more buffered soil all else being equal. This has been observed in grassland studies in Europe, where grasslands on poorly buffered acidic soils are more sensitive than grasslands on well-buffered calcareous soils (Maskell *et al.*, 2010). Abiotic factors may also affect the impact of direct toxicity, such as climate and base cation availability.

In systems where secondary stress dominates the ecosystem response to nitrogen deposition (e.g., through drought, frost, pathogens, herbivores, etc.), many of the same abiotic factors already mentioned above (e.g., climate and soil influencing the degree of N limitation affecting leaf palatability to herbivores and pathogens) operate to influence ecosystem sensitivity.

Biotic Factors Affecting Sensitivity

In addition to abiotic factors described above, several biotic factors affect sensitivity to N deposition (Dise, 2011; Gilliam, 2006). These biotic controls over the diversity response to N are in turn associated with the underlying mechanisms that alter changes in diversity.

Because growth and reproductive rates are linked with competitive ability, and not identical among competing

species, the differential ability to increase growth with N deposition affects local extinctions from competitive exclusion (Suding *et al.*, 2005). This variation in responsiveness to N is associated with adaptation to soil nutrient conditions (Aerts and Chapin, 2000). Species characteristic of infertile soils generally have low growth rates and low tissue nutrient concentrations, which lowers their demand for nutrients, and lowers the rate of supply during decomposition of senesced material, thereby promoting their own persistence. Species characteristic of fertile soils follow opposite patterns, with high growth rates and nutrient tissue creating conditions favorable for their persistence. Patterns of biomass allocation and the ability to form new meristems in response to variation in N supply is another important determinant of a species growth response (Bowman and Bilbrough, 2001). Woody species and forbs generally have a lower capacity to form new meristems relative to grasses.

These physiological patterns are likely responsible for reported shifts among functional response types and traits under N enrichment. For instance, N enrichment tends to favor grasses, especially annual and tall or shade-tolerant grasses, nonlegumes (legumes fix atmospheric N), sedges, and broad-leaved trees (Fynn and O'Connor, 2005; Xia and Wan, 2008). Conversely, forbs, legumes, and perennials may be competitively suppressed by N enrichment (Xia and Wan, 2008). Thus, a first order approximation of the potential losses of biodiversity is whether there are few or many sensitive species present. However, a species' risk of loss is not solely determined by its individual traits, but also on how those traits compare with the species around it. For example, annuals are expected generally to respond strongly to nitrogen deposition. However, in communities dominated by many annual species (e.g., California Mediterranean grassland) there is a relatively weak response because species are generally similar to one another. Contrast this to the strong response in the perennial-dominated (*Leymus chinensis*) mature steppe of China, which experienced a strong increase of previously rare annual species and reductions in diversity (Bai *et al.*, 2010).

The type of microbial association also appears to influence a species' growth response. Trees in the eastern US with arbuscular mycorrhizal interactions have a greater capacity to increase growth in response to N deposition than ectomycorrhizal species (Thomas *et al.*, 2010). Although N enrichment often suppresses arbuscular mycorrhizae more strongly than ectomycorrhizae because of reduced C from plant hosts (Treseder, 2004), this may not have been the case in Thomas *et al.* (2010) possibly because of low soil P. The growth of species with symbiotic N-fixing bacteria are usually limited by P or micronutrients such as molybdenum, and are generally more likely to experience local extinction with increases in N availability than species that are N limited (Suding *et al.*, 2005).

Species also vary in the degree to which N deposition affects their susceptibility to environmental stress and soil acidification. Generally evergreen species exhibit greater deposition-induced susceptibility to stress than deciduous species (Evans *et al.*, 2001; Sheppard *et al.*, 2008). Species buffer the soils in the vicinity of their roots through ion exchange, and regulate tissue nutrient balances through similar ion

exchanges, each of which may differ among species (Stevens *et al.*, 2011).

Although globally herbaceous species show a greater biomass response to N enrichment than woody species (Xia and Wan, 2008), within an ecosystem N enrichment may shift dominance among plant life forms in the opposite direction. For instance, in some Arctic tundra communities enhanced coverage of woody species occurs in response to greater N availability, leading to declines in herbaceous species (Bret-Harte *et al.*, 2008). In tropical secondary forest, combined enrichment with nitrogen and phosphorus (N + P) neutralized the negative effects of N-only enrichment, associated with dramatic grass biomass responses to N + P (Siddique *et al.*, 2010). Thus, although there are some patterns that appear regularly in the literature, site-specific responses are dependent on many interacting processes that can yield a variety of patterns.

Finally, N deposition may influence diversity through interactions between plants and consumers (Throop and Lerdau, 2004). Increases in deposition have the potential to mitigate losses associated with insect herbivory through increased plant production (Throop, 2005), but may also amplify losses through increased feeding rates and pest populations associated with increased amount and nutrient content of foliage (Throop and Lerdau, 2004; Xia and Wan, 2008). Differential responses in phenology may amplify competitive interactions in some systems. In a Mediterranean California grassland, N addition delayed the early activity and flowering of grasses and brought on earlier flowering for forbs (Cleland *et al.*, 2006), enhancing competition for these two functional groups. Thus, there can be a greater potential for interaction through pests, pollinators, and herbivores, as well as for soil nutrients.

Interactions with Other Factors

Site History

Disturbance and management history may modify a site's susceptibility to N deposition by shifting relative resource limitation in relation to N supply or demand, or changing soil pH (Bobbink *et al.*, 2010; Dise, 2011). Management factors altering the potential impact of N deposition include the history of N fertilization, burning, grazing, mowing, and modification of vegetation and soil properties. In systems that are strictly N limited, practices that further reduce N availability (e.g., fire, mowing), might be expected to enhance sensitivity to N deposition, whereas practices that increase N availability (e.g., historical N fertilization) might be expected to reduce sensitivity to additional deposition (Bobbink, 1998). However, availability of other resources such as light and P are also affected, thus responses may be far more complex. Grazing is an especially dynamic process, and can increase N availability (through urine and feces), as well as decrease N availability and increase light (through biomass removal). Although the former tends to reduce biodiversity, the latter tends to increase it (Collins *et al.*, 1998). Historical addition of lime (CaCO₃) would likely reduce sensitivity to acidification and subsequent cation depletion. In total, there are numerous factors related to site history that can modify the impact of nitrogen deposition on the biodiversity of a particular area.

Can Systems Naturally Recover from Nitrogen-deposition Induced Changes in Biodiversity?

The potential for terrestrial biodiversity to recover following reductions in N deposition is an active and relatively new area of research. As described above, few studies have examined the impacts of added N on biodiversity at levels of N input comparable to N deposition; and, even fewer have examined recovery patterns. Nonetheless, a handful of studies globally are beginning to yield critical information.

For plants, three factors may slow or prevent biodiversity recovery (Bakker and Berendse, 1999; Clark and Tilman, 2010). First, long term N addition may increase N cycling via increases in plant and soil N content, and changes in plant community composition toward more N-rich species (Figure 7). Thus, merely stopping N deposition may not effectively reduce N cycling. Second, the availability seeds or propagules of the original species may be limiting, slowing their reestablishment. Third, acidification, toxic mineral buildup, and depletion of base cations could make a region unsuitable to the original species. In grasslands, accumulated litter can also inhibit germination through reducing light levels at the soil surface (Facelli and Pickett, 1991).

A large scale experiment in a Dutch pine forest that reduced N deposition via shelters found after 6 years that nitrogen leaching losses decreased, fungal populations increased, and pine growth and cation balance increased (Boxman *et al.*, 1998). Some other studies have reported similar trends, although others have not (Dise, 2011). For example, in two Swedish forest sites, fungal populations and understory vegetation were still degraded even though nitrogen fertilizer treatment had ceased for 9 and 47 years (Strengbom *et al.*, 2001). Other studies from the US and Europe have found that some important N cycling processes remained elevated 8, 10, 14, and 25 years after treatments ceased to heathland, prairie, short-grass steppe, and a northeastern forest (reviewed in Clark *et al.*, 2009). An analysis of recovery in a UK heathland found that whereas shoot length, soil pH, and lichens had generally recovered, plant phenology, soil N, and soil microbial activity had not (Power *et al.*, 2006). Analyses of soil seed banks suggest that seeds of many target species (e.g., perennial forbs) do not survive more than a few years to a decade in the soil, and their germination can be suppressed after long-term nitrogen deposition (Thompson *et al.*, 1998). Thus, unless there are refugia nearby of target populations, once lost from the landscape, species recovery may be particularly slow.

Much less is known about how species other than plants and soil biota may or may not recover following reductions in N deposition. For insects and other animals, it is generally assumed that recovery of the plant community would promote recovery in the insect and animal communities. However, especially for large and/or nonflying animals, recovery may be additionally impaired by their ability to move to the recovered habitat. With extensive modification of the landscape from agriculture and urbanization, such movement may be difficult.

It is clear that the recovery potential varies widely among systems and for different processes within systems. Generally, recovery strongly depends on the degree of degradation that has occurred, and the strength of the aforementioned

processes in maintaining the degraded community. It appears that fast-cycling processes such as nitrate leaching and plant nutrient concentrations may recover fairly quickly, whereas slower cycling processes such as decomposition and plant populations might recover much more slowly if at all. Thus, recovery of terrestrial biodiversity over time scales of interest to land managers (years to a few decades) may require management intervention (Dise, 2011).

Management Options to Prevent Degradation and Restore Biodiversity

Monitoring and Modeling

Monitoring networks that measure N deposition rates have been established within the US through the Environmental Protection Agency's (EPA) National Atmospheric Deposition Program (NADP) and the Clean Air Status and Trends Network (CASTNET), and in Europe through the European Monitoring and Evaluation Program (EMEP). These networks provide national scale data on rates of nitrogen deposition. Similar networks are rare in the rest of the world, with only scattered monitoring stations available in most other regions. These networks are critical toward advancing our understanding of nitrogen deposition. Nonetheless, they do have limitations, including: (1) not all nitrogenous species are measured (e.g., NH_3 , organic N), (2) not all mechanisms of deposition are accurately and regularly assessed (esp. dry and fog deposition), (3) monitoring stations are generally lacking in remote areas or areas with complex terrain (Pardo *et al.*, in press; Weathers *et al.*, 2006). Several modeling efforts have been developed to try and address some of these issues (esp. the sparse coverage), including the EPA's Community Multi-scale Air Quality (CMAQ). These models are complex three-dimensional atmospheric transport and chemistry models that simulate deposition from emission sources to deposition sites. Though these modeling efforts are major contributions, they are also limited by our own understanding of process and by a lack of data to calibrate modeling runs.

Critical Loads

In Europe work has been ongoing over the past few decades to establish critical loads for atmospheric pollution under the framework of the Convention on Long-range Transboundary Air pollution (Dise, 2011). Critical loads are defined as "a quantitative estimate of an exposure to one or more pollutants below which significant harmful effects on specified sensitive elements of the environment do not occur according to present knowledge (Nilsson and Grennfelt, 1988). They are used as a guide to determine when and where ecosystems are vulnerable to degradation. Potential end points include enhanced leaching of soil nitrate, soil acidification, losses of biodiversity, and changes in species composition. Generally, critical loads for biodiversity are estimated based on empirical estimate, using experiments and observations (Bobbink *et al.*, 2010; Pardo *et al.*, in press). Models have also been employed that include biogeochemical cycling models and/or vegetation models (De Vries *et al.*, 2010). Similar efforts in the US have

been much less developed until only recently (Pardo *et al.*, 2011, in press). A summary of these critical loads for the US and Europe is shown in Figure 9. For many systems, the critical loads in the US are estimated to be lower than in Europe, perhaps because the EU has experienced high N deposition levels for longer periods, with observed systems already impacted and changes only being detectable at higher input rates (Dise, 2011; Pardo *et al.*, in press). In either case, much of Europe and the Eastern US experience N deposition at or above suggested critical loads.

Critical loads can be an effective tool for protection of biodiversity when are used to guide air pollution regulatory policy. Application of critical loads in Europe has connected science to policy by providing scientific methodologies to define pollution limits and to assist in setting reduction targets within a broad multinational policy framework. In the US, nitrogen critical loads are only beginning to be developed nationally, and are not currently used as a basis for regulatory policy. Efforts are underway to set a secondary standard for SO_2 and NO_2 concentrations based on ecological effects under the National Ambient Air Quality Standards in the US. However, terrestrial biodiversity impacts may not be included in setting secondary standards, largely because of insufficient data for setting N deposition thresholds for terrestrial biodiversity effects in the US.

Intervention and Policy

Intervention approaches generally aim to either reduce N deposition or enhance recovery. Reducing N deposition can occur through many policy approaches, including the establishment of the aforementioned critical loads, and through allowing tradable permits for pollution which are slowly removed from the market (thereby reducing pollution). An example is the Clean Air Markets Division of the US EPA. In many countries emissions and deposition of NO_x (and especially SO_x) have decreased in the past 20 years as a result of regulatory policies. However, similar controls for emissions of ammonia are less prevalent and the proportion of N deposition occurring in reduced forms (NH_x) is increasing in many areas above levels known to have ecological effects on sensitive taxa (Clarisse *et al.*, 2009; Fenn *et al.*, 2010). This highlights that special consideration as to which receptor to use is required prior to implementing critical loads. Plant and lichen biodiversity are impacted at lower air pollution levels than for human health impacts, and nonvascular biodiversity impacts are generally lower than vascular biodiversity impacts. Thus, when air pollution standards are determined primarily or solely by human health impacts, in many cases sensitive ecosystems and biodiversity will not be effectively protected.

Reduction of N deposition, however, may not be sufficient after decades of exposure rendering management efforts as necessary to promote recovery. Recovery can be promoted generally through two processes: (1) restoring the nitrogen cycle and other resource conditions to their predeposition state, and (2) enhancing the growth and productivity of target species of value. Restoring the nitrogen cycle can be fairly difficult, because many ecosystems are very efficient at retaining this critical nutrient (Chapin *et al.*, 2002; Vitousek

Figure 9 Comparison of critical loads from the US and Europe (Pardo *et al.*, in press, 2011). Included in the bars are many target receptors for nutrient nitrogen (e.g., nitrate leaching, plant biodiversity decline, etc.). Reproduced from Pardo LH, Fenn M, Goodale CL, *et al.* (2011) Effects of nitrogen deposition and empirical nitrogen critical loads for ecoregions of the United States. *Ecological Applications* 21: 3049–3082.

et al., 2002). However, several approaches have been explored to decrease nitrogen availability and restore predeposition conditions including increasing N export through harvesting or fire, increasing N leaching to the groundwater through flushing with aqueous solutions, and decreasing N availability through the addition of carbon (Bakker and Berendse, 1999; Blumenthal *et al.*, 2003). The addition of a carbon source to the soil often triggers soil microbes to take up soil N, thereby decreasing N availability to plants. Other soil and ecological conditions may have to be restored to promote recovery, including increasing pH through the addition of lime, or decreasing pest pressures through application of pesticides. However, restoration of nitrogen, soil, and other ecological conditions has no guarantee that the original species will return. This is more of a concern for grasslands than for forests, because forests respond much more slowly and have not generally experienced large changes in composition (Pardo *et al.*, in press). Because adults of grassland species may no longer be present in the regional landscape, and seeds in the seedbank may no longer be viable, seed addition may be required. For example, in experimental plots in Minnesota and in Kansas, seed addition was required to increase the biodiversity of target species even though individuals in undisturbed areas were less than a few hundred meters away (Clark and Tilman, 2010; Foster *et al.*, 2007). An experiment in Minnesota that

isolated the effects from several aforementioned mechanisms found that seed addition and successful germination led to the greatest recovery of biodiversity; and, studies from Australia and the Netherlands found that restoration of soil conditions was not sufficient to induce community recovery.

In total, research suggests that reduction in N deposition is a necessary, but possibly not sufficient, condition for recovery of terrestrial biodiversity. Additional intervention to restore soil conditions and/or plant populations may be necessary (esp. for nontree species), depending on many plant, soil, and ecosystem characteristics.

Conclusions and Next Steps

Nitrogen deposition, along with habitat losses and climate change, is known to be a primary threat to terrestrial biodiversity worldwide. Plant and animal biodiversity usually decline with elevated N in most biomes around the world. However, there is substantial variation in the magnitude of response from system to system and taxa to taxa, depending on many characteristics that influence ecosystem exposure and sensitivity to this critical nutrient. It is unknown to what degree recovery of biodiversity is likely if policies are put in place (or strengthened) to reduce deposition. Greater international coordination of research efforts

and policy design, especially in the area of impacts assessment and critical loads estimation, could enhance management of the impacts of nitrogen on terrestrial biodiversity.

Glossary

Biofuel Wide range of fuels that are in some way derived from biomass.

Endosperm Nutritive storage tissue in the seeds of most angiosperms.

Epiphyte Plant that grows on another plant nonparasitically or sometimes on some other object.

Hectare (ha) Area equal to 2.47 acres.

Mesocarp Botanical term for the middle layer of the pericarp – for example, comprising the flesh of fruits such as plums and cherries.

Monoecious In the current context, having male and female flowers on the same plant.

Oil Palm: Green Gold or Great Evil?

An Introduction to the Green Gold

Few topics provide as much controversy in tropical forest and wildlife conservation as the rapid expansion of oil palm (*Elaeis guineensis*) plantations. On the one hand, oil palm has been linked to deforestation, peat degradation, biodiversity loss, forest fires, and a range of social issues (Danielsen *et al.*, 2009; Koh and Wilcove, 2008, 2009; Sheil *et al.*, 2009; Sodhi *et al.*, 2010). On the other hand, oil-palm expansion is considered a powerful driver of economic development in tropical countries with low levels of welfare (Casson, 2000; McCarthy and Zen, 2010; Sheil *et al.*, 2009; World Growth, 2011), and it has been referred to as “green gold” (Friends of the Earth, 2008). Economic development can lead to reduced levels of forest loss, and biofuels from oil palm can reduce global carbon emissions, but the unanswered question is whether, at a global scale, do the benefits of oil palm outweigh the environmental costs? With much of Earth’s species diversity residing in tropical areas where oil palm thrives, there seems ample reason to closely assess the role that oil palm has played in tropical deforestation and loss of wildlife. Here the authors review the role of oil palm in biodiversity loss and conservation by assessing its impacts over a range of different spatial scales and in different socioecological contexts.

Basics

The origin of oil palm lies in the tropical rain forest region of West Africa in a region about 200–300 km wide along the coastal belt from Liberia to Angola (Duke, 1983). It has been described as “probably the most useful tree in West Africa” (Irvine, 1961). In prehistory, the palm was likely spread by people to a much larger area in Africa, ranging from 16° N latitude in Senegal to 15° S in Angola and eastward to the Indian Ocean, Zanzibar, and Madagascar. It has also been introduced and cultivated outside Africa and now occurs throughout the tropics between 16° N and 16° S latitudes. A distinct, closely related species of the oil palm, *Elaeis oleifera*

(also known as *Elaeis melanococca*), is indigenous to Latin America. We will limit our discussion to the African species and refer to it as “oil palm.”

Oil palm is a pioneer species that historically appears to replace evergreen rain forest under drier climatic conditions. For example, during the mid-Holocene in western Africa, changes in African monsoon conditions, decreased humidity, and increased fire led to the contraction of wet, evergreen rain forest and the expansion of woodland savannas. On these more-open savanna-type lands, oil palms were the dominating species (Maley, 2002; Ngomanda *et al.*, 2009; Salzmann and Hoelzmann, 2005). These vegetation shifts occurred alongside relatively “warm” regional and global conditions and could be an “analog” to events that might occur under global warming (Maley, 2002). Land clearance and burning act to increase the conditions under which oil palm thrives (Sowumni, 1999).

When fully grown, oil palms are tall, erect, single-stemmed trees that vary in heights from 8 to 20 m, with a stem diameter of as much as 50 cm. The tree is monoecious, with male and female flowers in separate clusters but on the same tree. Ecologically, this is a species of riverine forests and freshwater swamps that can tolerate temporary flooding and a fluctuating water table. The species does not do well in closed forest conditions and requires adequate light and generally open canopy conditions. It grows best in lowland areas with 1780 to 2280 mm rainfall per year, with a 2–4 month dry period, and a mean minimum temperature of 21–24 °C, but the species is adaptable and with proper care can be grown in climatic conditions outside these ranges (Duke, 1983). Its ecological adaptability is also clear from the wide range of tropical soils on which the species grows and thrives, with only waterlogged, highly lateritic, extremely sandy, stony, or peaty soils providing suboptimal growth conditions. Considering the rapid expansion of oil palm into Indonesian and Malaysian peat swamp areas (Koh *et al.*, 2011), it seems clear that even these acidic and often waterlogged conditions under appropriate silvicultural care provide suitable growing conditions for oil palm (Sheil *et al.*, 2009).

The use of oil palm by early humans is well known from the archeological record. Such uses date back to at least 4000

years BP (Logan and D'Andrea, 2012), and it appears that people in West Africa were actively cultivating oil palm as early as 3600–3200 BP (D'Andrea *et al.*, 2007). These early people were likely encouraging the growth of oil palms and achieving higher yields by clearing land (Logan and D'Andrea, 2012). Oil palm was a “camp follower” because of its ability to regenerate from discarded seeds without any particular horticultural treatment (Zeven, 1972). It was also traded widely, as indicated by finds of palm-oil residues in 5000-year-old Egyptian tombs (Friedel, 1897) far from where the oil was likely produced.

In Africa, palm oil has many traditional uses (Maley and Chepstow-Lusty, 2001). A few written records of the local food use of a palm oil (presumably from *Ela. guineensis*) are available in accounts of European travelers to West Africa from the middle of the fifteenth century (Hartley, 1988). One source describes how oil is produced from seeds by boiling, as well as how the oil-palm kernels are roasted and either eaten directly or made into flour (De Hondt, 1749). Palm oil later became an important item in the provisioning trade supplying the caravans and ships of the Atlantic slave trade, and it apparently remains a popular foodstuff among people of African descent in the Bahia region of Brazil (Northrup, 1978). Palm oil also found its way to Europe. James Welsh first brought 32 barrels of palm oil to England in 1590, and use grew rapidly after that. By the early nineteenth century, palm oil was being used to make soap and candles; later it was used for heating and cooking and in many other products from dynamite to margarine (Henderson and Osborne, 2000).

The increasing commercial use of palm oil is shown in early trade data. In the 1840s, the West African regions of Dahomey and the Niger delta exported approximately 1000 and 13,000 tons per year, respectively; by the 1880s these totals had risen to 5000 and 20,000 (Kiple and Ornelas, 2011). After 1900, European-run plantations were established in Central Africa and Southeast Asia, and the world trade in palm oil continued to grow slowly, reaching a level of 250,000 tons per year by 1930 (Hartley, 1988), still only about 0.5% of what was produced in the early twenty-first century (*see* The Modern Expansion).

The Modern Expansion

Plantations throughout Southeast Asia originate from the seeds of only four trees planted in Java, in present-day Indonesia, in 1848 (Henderson and Osborne, 2000). In 1905, a Belgian agricultural engineer, Adrien Hallet, arrived in Sumatra, another Indonesian island, and noticed that local palms that had originated from the small Javan gene pool grew more quickly and bore a richer fruit than counterparts in the Congo, where he had previously worked (Leplae, 1939). It was obvious that under Asian equatorial conditions, the locally cultured palms held a distinct advantage over the ordinary palms of Africa (Kiple and Ornelas, 2011). Reduced seasonality in island Southeast Asia compared to west Africa has a big impact on yield, with any drought (or even loss of humidity) reducing fruit set. Also, the fact that all the Asian palms were descended from so few parents meant that the early planters could expect fairly uniform results (Kiple and Ornelas, 2011), ensuing easier management. This lowered the risks associated with plantation cultivation, an effect reinforced by the absence of the palm's

usual pests and diseases in its new geographic setting. The success of oil palm was quickly noted in neighboring Malaysia, and the first plantations were established in peninsular Malaysia in 1917. By 1919, more than 6000 ha had been planted in Sumatra, rising to 32,000 in 1925, by which time 3400 ha had come under cultivation in Malaysia. Over the next 5 years, a further 17,000 ha were planted in Malaysia, whereas the Sumatran area doubled (Kiple and Ornelas, 2011). By 1998, palm oil contributed more than 5% to Malaysia's gross domestic product (Yusoff, 2006).

Oil-palm seeds were introduced to Central America by the United Fruit Company, which brought seeds from Sierra Leone to Guatemala in 1920, and from Malaysia to Panama in 1926 and Honduras in 1927 (Kiple and Ornelas, 2011). Other introductions from Java and the Belgian Congo followed, but the first commercial planting of 250 ha only took place in Guatemala in 1940. In its tropical American setting, the oil palm, however, proved vulnerable to disease – possibly due to the native American species being almost the same – and difficulties were encountered in identifying suitable growing conditions (Hartley, 1988). By 1992, the total area of oil palm planted in Latin America had grown to 390,000 ha. This is a small fraction of the area in Africa and Southeast Asia (Kiple and Ornelas, 2011), but oil-palm production in the neotropics is viewed by many as a major new force for land-use change and forest conversion in that region.

Production of palm oil in Indonesia rose from 168,000 tons grown on 105,808 ha in 1967, to roughly 16.4 million tons grown on 6.2 million ha in 2006 (Sheil *et al.*, 2009). By 2011, an annual production of 25.4 million tons was estimated for Indonesia, 18.4 million tons for Malaysia, 1450 tons for Thailand, 880 tons for Colombia, and 850 tons for Nigeria, with an additional 3281 tons from a range of countries, adding up to a global production of 50.3 million tons (USDA, 2011). Palm oil takes up about 10% of the global production of vegetable oils, which remains dominated by soybean oil (USDA, 2011). These figures suggest that Indonesia alone underwent a 150-fold increase in palm oil production in 34 years.

Currently, Indonesia is the world's largest and most rapidly growing producer. Indonesia's wet tropical climate provides ideal growing conditions for oil palm. Land is abundant, and labor is cheap (Sheil *et al.*, 2009). About 10% of Indonesia's palm oil production comes from government plantations, 40% from small holders, and 50% from private plantations (IPOC, 2006). Malaysia is the world's second-largest individual palm oil-producing nation. Together, Indonesia and Malaysia account for about 90% of crude palm oil produced globally per annum (Sheil *et al.*, 2009). In the Southeast Asian region, a total of 8.3 million ha of closed canopy oil-palm plantations occur in peninsular Malaysia (2 million ha), Borneo (2.4 million ha), and Sumatra (3.9 million ha) (Koh *et al.*, 2011), suggesting that oil palm takes up about 6.2% of the total landmass of these three regions. We note that the study by Koh and colleagues was unable to detect newly planted oil palm, so that total area of oil palm may be larger.

As a region, Africa is the second-largest producer of oil palm in the world. Data from the Food and Agricultural Organization's FAOSTAT database indicate that about 4.5 million ha of productive oil-palm plantation existed on the continent

in 2009. Some 71% of African oil palm is produced in Nigeria, with Ghana, Guinea, Côte d'Ivoire, and the Democratic Republic of the Congo being other important producers.

In addition to Africa and Asia, oil-palm production is also rapidly expanding in the neotropics, with some 700,000 ha of productive plantation in 2009 (FAOSTAT data). Nearly half of the Amazon basin, around 2.3 million km², appears suited in terms of climate and soils for oil-palm cultivation (Stickler *et al.*, 2008). Even though the total oil-palm area remains small compared to Asia, the mean annual rate of expansion was an astonishing 7.9% between 1991 and 2001 (Bolivar and Cuellar-Mejia, 2003). Large-scale plantations are already established in Colombia, Ecuador, and Brazil, although the latter was only the world's 14th biggest producer of palm oil in 2009. If the full potential of the Amazon basin was utilized, however, Brazil alone could dwarf the current production of Asia (Butler and Laurance, 2009). Oil-palm planting has been promoted in Colombia, where it is seen as a relatively profitable alternative to cocaine (Gómez *et al.*, 2005). To differentiate it from the less-productive but similar native species *Ela. oleifera* (see Uses) *Ela. guineensis* is commonly referred to as the "African palm" or "dendezeiro" (Lopes and Steidle Neto, 2011). As in Asia, oil palm is viewed as a crop that can be profitable under many different levels of management intensity (including small-holders) in a wide range of contexts (Wolff, 1999). However, there are concerns over disease – though it is likely that breeders will be able to develop healthier and more-resistant varieties and hybrids (de Franqueville, 2003).

Uses

In well-managed plantations, oil palm produces 3–8 times more oil from a given area than any other tropical or temperate oil crop (Sheil *et al.*, 2009; Yusoff, 2006). Oil can be extracted from fruit and seed, palm-fruit oil from the outer mesocarp, and palm-kernel oil from the endosperm. Most palm-fruit oil is used in foods. In contrast, most palm-kernel oil is used in various nonedible products such as detergents, cosmetics, plastics, surfactants, and herbicides, as well as in industrial and agricultural chemicals (Wahid *et al.*, 2005). The use of palm oil as a biofuel is also increasing (Persson and Azar, 2010), giving oil palm an aura of environmental sustainability. In fact, if biodiversity losses from land-use changes are disregarded, oil palm is one of the most environmentally sustainable among a range of global biodiesel and ethanol crops (de Vries *et al.*, 2010). Together with sugarcane grown in Brazil and sweet sorghum grown in China, oil palms makes the most efficient use of land, water, nitrogen, and energy resources, whereas pesticide applications are relatively low in relation to the net energy per hectare produced (de Vries *et al.*, 2010).

The traditional red palm oil produced by West African village methods has a wide range of applications. It is mostly used for food (Kiple and Ornelas, 2011). This type of oil, however, has not proved suitable for food use in the importing countries of the West, where consumers require a bland, nearly white cooking fat. Today's plantation-produced palm oil can be treated to meet Western requirements, but this was not possible before the early twentieth century (Vanneck and Loncin, 1951). Once technology had advanced enough, European food manufacturers could exploit palm oil,

replacing more-expensive fats such as butter, beef tallow, and lard in central and northern Europe and olive oil in southern Europe (Kiple and Ornelas, 2011). Palm oil was suitable as both liquid oil and solid fat.

Since the late 1960s, plant breeders have taken an interest in the American oil palm *Ela. oleifera* because its oil has a high iodine value and unsaturated fatty acid content, making it especially suitable for food use (Kiple and Ornelas, 2011). However, the fruit is often small, with a thin, oil-yielding mesocarp surrounding a large, thick-shelled kernel. Harvested bunches often contain a low proportion of fruit of quite variable quality. Hybrids between *Ela. guineensis* and *Ela. oleifera* have been trialed and show some advantages over *Ela. guineensis*, despite higher production costs (Amblard *et al.*, 1995).

Concern over greenhouse gases and high prices for fossil fuel have spurred interest in biofuels and alternative sources of energy. Biodiesel from palm oil (palm oil methylester) is currently leading the pack, and major investments are already planned to convert millions of hectares of tropical forests and other land types to oil-palm plantations (Sheil *et al.*, 2009).

Biofuels may have major positive or negative effects on natural forests, forest dwellers, and owners. On the one hand, biofuel from oil-palm plantations could help to promote economic prosperity and alleviate poverty (World Growth, 2011). On the other hand, demand for biofuels could increase competition for land, threaten food production, and exacerbate inequities between rich and poor (Astyk, 2006). Whether or not the use of palm oil as biodiesel yields a net reduction of greenhouse gas emissions remains debated (de Souza *et al.*, 2010; Gibbs *et al.*, 2008) but depends a lot on the type of vegetation that existed prior to oil-palm development.

High global demand feeds the current oil-palm boom. Despite many anti-oil palm campaigns targeting palm-oil consumers and importing countries, it is likely that the sector will expand further, either in Southeast Asia or, if the land bank becomes limited there, in the African and American tropics. At current prices, it has recently been estimated that the opportunity costs of conserving forests in Southeast Asia are US \$9860–12,750 ha⁻¹ from logging and a further US \$11,240 ha⁻¹ from subsequent conversion into oil palm plantations (Fisher *et al.*, 2011). Others have argued that these figures are overly pessimistic (from a forest conservation point of view) and that payments for carbon sequestration and other environmental services such as clean water supply from forests could realistically offset the opportunity costs of forest development (Ruslandi *et al.*, 2011; Venter *et al.*, 2009).

Production in Small-Holder and Large-Scale Contexts

Oil-palm seedlings are typically raised in a nursery for 1 year before planting out. Planting densities range from 110 to 150 stems per ha (Basiron, 2007). In small-holder settings in Africa, planting densities can be considerably higher; densities of 200 palms per ha were common in the late 1940s, and densities of more than 300 palms per ha were not unknown (Hartley, 1988). Most commercially used oil palms mature rapidly, and fruit can be harvested only 2–3 years after planting (Basiron, 2007) although 9–15 year old trees are most productive (BisInFocus, 2006). After 25–30 years, trees become too tall to harvest and are replaced. Some long-established

plantations in Malaysia have already been replanted for the third time (Basiron, 2007).

Labor input over the life of an oil-palm project is about 1397 person day per ha in Southeast Asia; divided by 25 years, this suggests that on average each hectare of oil palm has someone working on it – and thus earning income – 56 days of the year (Ginoga *et al.*, 1999). Unlike most other crops, oil-palm production is not very seasonal, allowing more-efficient, year-round use of labor.

Once harvested, fruit deteriorates rapidly and must be processed within 24 h (Vermeulen and Goad, 2006), so access to a mill is a major factor in determining where commercial plantations can be established. Palm-oil production is therefore most efficient when the crop is grown in a large monoculture around a central processing mill rather than in small holdings interspersed with other vegetation (Maddox *et al.*, 2007). The development of small-scale floating mills may allow companies to plant and process oil-palm fruits in remote areas at smaller scales, but such initiatives have not been taken up yet and are presumably less cost-effective than large-scale plantations.

Public Perceptions

Oil palm is hotly debated. Any internet search on keywords “orangutan” and “oil palm” reveals a plethora of mostly negative attitudes toward this palm and the people behind its boom. Internet titles such as “Palm oil costs the lives of about 50 orangutans every week and its cultivation is a major cause of global warming” and “Orangutans struggle to survive as palm oil booms” further suggests that conservation and oil palm are not happy bed fellows (EIA, 1998; Robertson and van Schaik, 2001; World Growth, 2009). Oil palm has its proponents too, however. These proponents not only include obvious ones such as palm oil producers and their support organizations but also the national governments of Indonesia and Malaysia, which earn significant revenues from palm oil production. It is becoming increasingly clear that small-scale farmers in these countries prefer oil palm to other crops because of high relative returns (Feintrenie *et al.*, 2010; Rist *et al.*, 2010). The strongly divergent viewpoints about the environmental and social costs of oil palm versus its benefits (Koh *et al.*, 2009; Meijaard and Sheil, 2011) has resulted in a situation in which middle-ground solutions of minimizing oil palm’s impact have become increasingly difficult (Meijaard, 2010). The situation is not helped by the significant disinformation created on both sides of the debate (Koh and Wilcove, 2009; Sheil *et al.*, 2009). Better science-based information about the positive and negative impacts of oil palm over different temporal and spatial scales is urgently needed for more-informed discussion on the impact of this palm on global biodiversity (Sheil *et al.*, 2009).

Oil Palm and Biodiversity

Value as Wildlife Habitat

Not all aspects of biodiversity are negatively impacted by oil palm, and oil-palm plantations have some conservation

benefits. Similar to fig and nectar, palm nuts are considered to be keystone ecological resources, providing crucial links between plant and animal communities (Terborgh, 1986). For example, in its native West Africa, oil palm provides important resources to the chimpanzee (*Pan troglodytes verus*) (Humble and Matsuzawa, 2004; Leciak *et al.*, 2005; Sousa *et al.*, 2011). This mostly occurs in patchy oil-palm groves in a matrix of agricultural land and forests rather than the extensive areas of single-species oil-palm plantation generally found in Asia. Chimpanzees seem to prefer oil palms for building their sleeping platforms or “nests,” even when they have access to natural forests; they also use palm fruits as fallback resources (Sousa *et al.*, 2011).

Other African species that feed on oil palm include Thomas’s rope squirrels (*Funisciurus anerythrus*) (Pettet, 1969); white-throated bee-eaters (*Merops albicollis*), which catch and eat the epicarp of the fruit dropped by the squirrels (Fry, 1964); southern yellow-billed hornbills (*Tockus leucomelas*); and the aptly named oil-palm vulture (*Gypohierax angolensis*) (Landsborough and Moreau, 1957). Black vultures (*Coragyps stratus*) in northwestern Colombia feed heavily on oil-palm fruit and appear to prefer it to carrion (Elias and Dubost, 1982), whereas several raptor species that feed on rats thrive in oil palm in Honduras (Padilla *et al.*, 1995). In Central America, the white-faced capuchins (*Cebus capucinus*) are well-known users of oil-palm areas (McKinney, 2010; Williams and Vaughan, 2001).

Southeast Asian oil-palm areas also provide resources to certain species, and many species use the oil-palm matrix to move between forest patches, something they might not do in plantings of annual crops or grasslands. A study in Sumatra showed a wide range of species inhabiting the area of an oil-palm plantation, with 40 mammals listed in total (38, not including domestic species) (Maddox *et al.*, 2007). Of these, 63% have an important conservation value or are protected under national law, and 25% are listed as vulnerable or higher on IUCN red lists. The tiger was the most endangered species recorded on site, rated as critically endangered. Asian elephants (*Elephas maximus*) and dhole or wild dog (*Cuon alpinus*) are the next most endangered. Tigers (*Panthera tigris*) and leopards (*Panthera pardus*) in peninsular Malaysia frequently move into oil-palm estates from surrounding forest areas to prey on wild ungulates such as pigs and deer or on domestic cattle (Azlan and Sharma, 2006). In fact, a study in peninsular Malaysia suggested that a hyperabundance of the banded pig (*Sus scrofa vittatus*) in a forest reserve surrounded by oil palm was caused by abundant year-round food supply of oil-palm fruits from the extensive plantations bordering the reserve (Ickes, 2001). The presence of prey species in oil palm is both a benefit and threat to large predators (*see* Charismatic Species).

Considering that oil palm produces highly nutritious nuts, it is surprising that few records exist of Southeast Asian species feeding on oil palm. There are indications that orangutans occasionally eat oil-palm nuts (M. Ancrenaz, pers. comm.), but such use is not extensively documented. Considering that chimpanzees use these fruits extensively, it may just be a matter of time until orangutans similarly learn to do so. Observations in Sumatra suggest that both long-tailed (*Macaca fascicularis*) and pig-tailed (*Macaca nemestrina*) macaques feed

extensively on fallen palm fruit, as do pig species (both *S. scrofa* and *Sus barbatus*) (EM, pers. obs.). A lot more records of species feeding on oil palm are available in the literature on pest species. A book on pest species that affect oil palm globally (Hill, 2008) lists squirrels (*Callosciurus* spp.), rats (*Rattus* spp.), various parrots and parakeets, porcupines (*Hystrix* sp.), and a host of invertebrate species, such as the coconut case caterpillar (*Mahasena corbetti*), the African rhinoceros beetle (*Oryctes boas*), the coconut palm borer (*Melittomma insulare*), the palm leafminer (*Promecotheca cumingii*), the South American palm weevil (*Rhynchophorus palmarum*), and the African palm weevil (*Rhynchophorus phoenicis*). As documented in Southeast Asia, these invertebrates in turn attract bird species such as *Pycnonotus goiavier*, *Prinia* spp., *Parus major*, *Copsychus saularis*, and *Halcyon smyrnensis*, all species feeding primarily on insects and normally common outside forests (Desmier de Chenon and Susanto, 2006).

The obvious issue with some species in an oil-palm plantation context is that they cause damage to plants and palm nuts. For example, population densities of *Rattus tiomanicus* are between 100 and 600 animals per ha in Southeast Asian plantings of a range of ages and localities (Wood and Fee, 2003), and losses in Malaysian palm oil caused by these rodents were valued at US \$32 million annually in the 1980s (Basri and Halim, 1985). This benefits threatened species such as blood pythons (*Python brongersmai*) and short-tailed pythons (*Python curtus*) that feed on these rats, and which in Sumatra have increased in abundance because of the establishment of oil-palm plantations (Shine *et al.*, 1999).

Impact on Species Diversity

Most of the world's species diversity is concentrated in humid tropical forest (Hoffmann *et al.*, 2010; Leadley *et al.*, 2010), the ideal habitat for oil-palm fruit production. The expansion of oil palm is therefore most likely to directly impact tropical biodiversity. The same tropical region is also an area where the majority of people are primarily concerned with meeting their basic needs (Kaimowitz and Sheil, 2007; Millennium Ecosystem Assessment, 2005). Economic development in many countries in this region is driven by natural resource exploitation, adding to the pressure on remaining forest areas. With regard to oil palm, this is especially evident in Southeast Asia, where the largest areas have so far been developed. Indonesia and Malaysia's lowland forests are among Earth's most species-rich terrestrial habitats (Sodhi *et al.*, 2004; Whitten *et al.*, 2004). The loss of Southeast Asia's lowland forests threatens the region's exceptional conservation value (Curran *et al.*, 2004; Tinker, 1997) and has long been the principal conservation concern in the region (Jepson *et al.*, 2001).

Surprisingly, despite the apparent impact of oil palm on biodiversity, conservation science is a relative newcomer to this topic. A 2008 review of 678 publications on oil palm published over 35 years found that only six of the publications specifically addressed the biodiversity and species conservation aspects of oil palm (Turner *et al.*, 2008). Since that time, there have been many more scientific study of species diversity and abundance in oil palm.

Because of oil palm's light requirements, plantation development generally requires that all other vegetation is

removed. Oil-palm plantations are thus dominated by only one plant species (Danielsen *et al.*, 2009; Fitzherbert *et al.*, 2008; Gillison and Liswanti, 1999). Oil-palm plantations are also structurally less complex than natural forests, with a uniform tree age structure, lower canopy, sparse undergrowth, less-stable microclimate, and greater human disturbance (Danielsen and Heegaard, 1994; Fitzherbert *et al.*, 2008; Peh *et al.*, 2006), and they are cleared and replanted on a 25–30 year rotation (Sheil *et al.*, 2009). It is therefore not surprising that the floral and faunal diversity of these plantations is very low when compared to tropical lowland rain forests.

To give examples, researchers in the province of Jambi recorded 75% less plant diversity in oil-palm plantations than in natural forest (Gillison and Liswanti, 1999). Mammals are also affected, and a 4-year study of terrestrial mammals living in and around an oil-palm plantation concession in Jambi concluded that oil-palm monocultures are very poor habitats for most terrestrial mammal species (Maddox, 2007). Only four mammal species (10% of the number detected within the approximately 80,000 ha landscape) were regularly detected in the oil palm itself, and none of these species had a high conservation value. Some species, including deer (*Cervus unicorn*), macaques (*Macaca* spp.), and pangolin (*Manis javanica*) showed limited tolerance, but, with the exception of pigs (*Sus* spp.), all species showed a general preference for non-oil palm habitats – even heavily degraded forests (Maddox, 2007). In fact, the study highlighted the conservation importance of marginal or degraded habitats often found within palm-oil concessions and highlighted that these areas can retain high conservation values (Maddox, 2007).

Most studies of oil-palm biodiversity show large differences in faunal species composition between oil palm and forests (Fitzherbert *et al.*, 2008). The animal species lost tended to include species with specialized diets and reliance on habitat features not found in plantations (such as large trees for cavity-dwelling species) and also species with the smallest range sizes and those of highest conservation concern (Fitzherbert *et al.*, 2008). Plantation assemblages were typically dominated by a few abundant generalists, nonforest species (including alien invasives), and pests.

These findings of reduced species diversity in oil palm correspond with studies elsewhere. In Malaysia, researchers found that fewer than 20 of 75 mammal species encountered in primary forest also used oil palm (PORIM, 1994). Birds are also negatively affected, with one study in a 5000-ha study site of forests, oil palm, and agricultural lands reporting that conversion of forest to plantations resulted in reduced species richness of at least 60%, which especially affected threatened forest-dependent birds (Aratarkorn *et al.*, 2006). A review study of bird faunas in oil palms and forests found that although bird species richness is lower in oil palm than in forests, bird abundance does not appear to be. Species found in plantations are generally of lower conservation concern than those from forests (Najera and Simonetti, 2010).

Invertebrate communities in oil-palm plantations seem to be similarly influenced. Beetle assemblages in habitat types in Sabah, Malaysia, ranging from primary forest, logged forest, and acacia plantation to oil-palm plantation, had the lowest species diversity in oil palm, with a few species becoming numerically dominant (Chung *et al.*, 2000). Ant species

richness in Malaysian Borneo decreased from 309 to 110 species (–64%) between a 43,800-ha primary forest areas and a 2576-ha oil-palm plantation (Faile *et al.*, 2010), and oil palm can sustain only about 5% of the ground-dwelling ant species of the forest interior (Bruhl and Eltz, 2010). However, the impact of oil palm on species diversity was not the same across all microhabitats that were investigated, with bird's nest ferns occurring in both forests and oil palm maintaining almost the same number of ant species in both vegetation types. Species losses were much more pronounced in canopy and leaf-litter faunas (Faile *et al.*, 2010). Also, ant communities in oil palm are dominated by nonforest species, with nine of the 23 ant species baited in the plantations never having been recorded inside the forest (Bruhl and Eltz, 2010).

Species diversity *per se* may not always be a relevant measure for ecosystem health. A study of bee diversity in a range of vegetation types, including oil palm, in peninsular Malaysia found that the diversity in oil palm, as measured by a wide range of diversity and evenness indices, was considerably higher than in primary forest, although the absolute abundance of bees was much lower (Liow *et al.*, 2001). The 2500-ha monocultural oil-palm plantation had 17 species of bee, whereas the two natural forest sites (each >2000 ha) had nine and seven, respectively. The absolute number collected, however, was 64 for the oil-palm site and 419 and 444 for the natural forest sites. The authors suggest that absolute numbers of bees rather than species diversity may be more important for maintaining the ecosystem and ecological processes than the absolute number of species, because of their role in pollination.

A recent review of 13 studies summarized how species diversity in oil palm compared to that in other plantation crops (Fitzherbert *et al.*, 2008). Because of the small sample size, control for locations and context was not possible, and the review findings need to be interpreted with caution. Rubber (*Hevea brasiliensis*) supported as many or more species as oil palm and more forest species. Cocoa (*Theobroma cacao*) had similar or higher species richness but not always more forest species. Coffee (*Coffea canephora*) supported higher ant species richness and more forest species than oil palm. Rubber, cocoa, and coffee are often grown in small-holder settings or agroforestry landscapes. Compared to oil palm, their scale of development is generally smaller, and these crops often occur in a matrix of secondary forest regrowth. This might at least partly explain why their species richness is higher than in oil palm. *Acacia mangium* plantations, which are planted for pulp and paper, are generally developed as large (>10,000 ha) industrial plantations. In Indonesia, oil palm is established in monoculture plantations ranging in size from 4000 to more than 20,000 ha (Sheil *et al.*, 2009), which is on a scale similar to industrial tree plantations. Still, acacia plantations have higher beetle species richness than oil palm, and species composition is closer to that in forest (Chung *et al.*, 2000). Similar results were found for studies of birds, which in acacia and albizia (*Paraserianthes falcataria*) plantations resembled the avifauna of secondary forest regrowth, whereas oil palm attracted few bird species (Sheldon *et al.*, 2010).

Fitzherbert *et al.*'s (2008) review suggested that only pasture and urban mown grassland had lower species diversity than oil palm, whereas gardens of mixed crops had similar or

higher species richness, and abandoned pasture had more species than oil palm. *Imperata cylindrica* grasslands, a fire-induced vegetation type that commonly replaces deforested land, had more species of ants but fewer forest ant species than oil palm (Fitzherbert *et al.*, 2008). Compared to other monocultural plantation species that harbor significant native species diversity (Hobbs *et al.*, 2006; Lugo, 1992), oil-palm plantations appear to resemble the other extreme of exotic plantation species that have limited value to native biodiversity conservation (Mascaro *et al.*, 2008). The overall conclusion about biodiversity in oil-palm plantations is that, at a local scale, it is as low as the most degraded and human-altered tropical vegetation types and therefore has limited local conservation importance.

Charismatic Species

A number of species, including orangutans (*Pongo* spp.) and the Sumatran tiger (*P. tigris sumatrae*) are the focus of international concern. The conservation of these species is often mentioned in relation to the expansion of oil palm (Linkie *et al.*, 2003; Nantha and Tisdell, 2009; WWF, 2011), and these species have played an important role in shaping the public attitude toward oil palm. Although industrial oil-palm development has been ongoing for decades, it was not until the 1990s when environmental campaigns started to focus on the role that oil palm plays in the demise of iconic conservation species and their forest habitats that the public mood began to change. These campaigns initially focused on the impacts on orangutans (Buckland, 2006; EIA, 1998) but also addressed other species, primarily tigers and elephants (Friends of the Earth, 2005). The authors discuss the impacts of oil palm on these species relative to other threats.

Orangutans

The main impact of oil palm on orangutans is habitat loss, with human-orangutan conflicts associated with oil-palm development a secondary threat (Meijaard *et al.*, 2011, 2012). Orangutans are primarily arboreal creatures, using relatively large territories and mostly feeding on fruits, leaves, and barks originating from hundreds of plant species (Rijksen and Meijaard, 1999). In 2008 in Kalimantan, oil palm threatened 750,000 ha of orangutan forest, representing 5.5% of the Bornean orangutan distribution (Venter *et al.*, 2009).

Recent studies have shown unexpected ecological resilience in orangutans in selectively harvested timber concessions and plantations of *Acacia mangium* (Ancorenaz *et al.*, 2010; Meijaard *et al.*, 2010). Surprisingly, very few studies exist of orangutan use of oil-palm habitats. One report focuses on management and the avoidance of human-orangutan conflict in oil-palm areas (Yuwono *et al.*, 2007), but it does not clarify how orangutans are affected. A recent study in Sumatra investigated crop-raiding by a population of Sumatran orangutans (*Pongo abelii*) that had become isolated from natural forest in an agricultural landscape, including oil-palm plantations (Campbell-Smith *et al.*, 2011). This study showed that the oil-palm patches in this landscape offered few, if any, benefits to orangutans.

Aerial surveys in eastern Sabah, Malaysian Borneo (M. Ancrenaz, unpublished data), identified large numbers of orangutan nests in oil-palm plantations, especially in small forest patches within the oil-palm matrix. The size of these patches fluctuated from a single tree to a few hectares and the forest was highly degraded and lacked the typical forest structure. It was estimated that at least a couple of hundred individuals were using the oil-palm landscape at the time of the surveys.

As long as oil palm does not offer a food resource to orangutans and forest fragments within the oil palm are small, degraded, and few, it is doubtful that an oil-palm landscape can sustain a viable resident orangutan population in the long-term. The nests seen during aerial surveys were most probably built by “transient” orangutans that are roaming through the oil-palm estates in search of forest during their dispersal phase. Indeed, young males leave their native community when they become mature and establish their own territory in a new forest area (Goossens *et al.*, 2006). These orangutans are “connectors” in fragmented metapopulations, and oil palm could therefore have some benefits in maintaining overall connectivity.

Tigers

Tigers are threatened worldwide by habitat loss, reduction in prey, and hunting (Chundawat *et al.*, 2010) and in Malaysia and Indonesia also by expansion of oil palm (Linkie *et al.*, 2003). Like orangutans, tigers do reasonably well in selectively logged or otherwise degraded forests, but they favor areas with little human use (Linkie *et al.*, 2008). Compared to natural forests, oil-palm estates have relatively high human use. It is therefore not surprising that tigers have much higher densities in forest than in oil palm (Maddox *et al.*, 2007).

Tigers do use oil-palm areas, however, especially when these are adjacent to good-quality forest. The attraction is in the food resources such as deer, pigs, and also domestic animals. For example, tigers killed at least 60 cattle in a 27-month period in an oil-palm estate in peninsular Malaysia (Azlan and Sharma, 2006). Where large predators and oil palm coincide, this often leads to conflict and there are regular reports in Malaysian and Indonesian newspapers of oil-palm workers having been killed. Generally, tigers are unwelcome in oil palm and are often killed if they threaten workers (Brown and Jacobson, 2005). Also, crop predation by wild ungulates such as pigs and deer leads to crop protection measures, which often include nonselective techniques such as snaring, poisoning, and drive netting. These, in turn, harm or kill tigers and reduce their prey (Wibisono, 2005). In fact, it is thought that one of the main threats to the conservation of Sumatran tigers is the response to crop depredation by large ungulates in agricultural lands, including oil-palm plantations, near protected areas (Wibisono and Puspardini, 2010).

A recent study modeled extinction risk of Sumatran tiger in a landscape containing a protected area, logging concessions, pulp-wood plantations, agroforestry, oil palm, and settlements (Imron *et al.*, 2011). The study used information on tiger hunting and breeding behavior and found that the longest survival times occurred in mixed landscapes of protected areas, logging concessions, and pulp-wood plantations rather than models based on a single land use. Selectively logged forests

contributed most to the survival chances of tigers in the protected area, concurring what was found by Meijaard and Sheil (2008) elsewhere. The settlement and oil-palm plantation scenarios clearly showed the detrimental effect of these land-uses on tiger persistence. Both single land use and combined scenarios resulted in extinction within a relatively short period of time, confirming that oil-palm plantations do not provide good habitat for tiger prey, provide poor tiger habitat, and experience high human pressure, which lead to the absence of tigers (Imron *et al.*, 2011).

Asian Elephants

Asian elephants (*Ele. maximus*) are primarily a forest-edge species (Rood *et al.*, 2011), suggesting they prefer to feed on the type of vegetation found in disturbed areas. Potentially, this could include oil-palm areas, but the evidence for this is unclear. On the one hand, they are reported to avoid oil palm. In a study in Sumatra, elephants were only ever recorded once on the fringes of the oil palm (Maddox *et al.*, 2007). On the other hand, another study reported that elephants are considered to pose a risk to oil-palm plantations because they often destroy palms and feed on the oil-rich palm nuts (Susanto and Ardiansyah, 2003). In fact, it has been suggested that such agricultural conflicts may pose as big a threat to Asian elephants as habitat loss (Hedges *et al.*, 2005; Linkie *et al.*, 2007). An internet search reveals many stories of elephants causing damage to oil palm and dead elephants being found in or close to oil-palm plantations, several reportedly killed by poisoning. Often the conservation authorities assist local farmers and oil-palm companies by capturing elephants and either moving them to other areas or keeping them in captivity. Trials in Malaysian Borneo, where the tamer Bornean subspecies of *Ele. maximus* uses oil-palm areas to move between forest patches, show that the use of electrical fencing to protect small-holder crops combined with the replanting of forest corridors provides an effective means to reduce elephant conflict (Ancrenaz and Lackman, 2011). This is expensive, however, and may only work in small plots. Chili grease-covered fences may be a cheaper alternative (Hedges and Giunaryadi, 2010).

Beneficial Wildlife

Oil-palm estate managers actively promote the presence of some species because they increase the production of oil palm or at least make it cheaper. Owls and snakes are the most important among these beneficial species. Barn owls (*Tyto alba javanica*) have been widely encouraged in Malaysian oil-palm plantations to control rodent pests. They were formerly considered vagrants in peninsular Malaysia, but they became established following the increase in rats with the advent of oil-palm plantations (Lenton, 1984). It is estimated that a pair of barn owls together with their chicks consume around 1300 rats per year (Duckett and Karuppuah, 1989), but it apparently remains doubtful whether these owls truly regulate rodent populations or whether rodent populations are more strongly affected by other factors such as food supply (Puan *et al.*, 2011).

Certain species of snakes are also attracted to the many rodents and other species feeding in oil-palm areas (Akani *et al.*, 2008; Shine *et al.*, 1999), and some plantations actively use snakes to control rodents, although not as commonly as owls or baiting (Hafidzi and Saayon, 2001). How effective such pest control is remains unclear.

Exclosure studies in Sabah, Malaysia, show that insectivorous birds deliver a natural pest-control service for oil-palm agriculture (Koh, 2008a). Where birds were excluded from oil-palm seedlings, herbivory rates from insects increased between 1.2- and 17.2-fold – significantly higher than that in control treatments.

Koh (2008a) reports that many companies adopt an integrated pest-management approach that favors the use of nonchemical pest control methods such as the establishment of “beneficial plants” (e.g., *Euphorbia heterophylla*) to attract the insect predators and parasitoids of oil-palm pests such as the wasp *Dolichogenidea metesae* (Basri *et al.*, 1995).

Finally, the native pollinator of oil palm (the weevil *Elaeodorus kamerunicus*) did not originally occur in Asia. When it was introduced from Africa, production increased and the cost of artificial pollination was saved (Dhileepan, 1994; Southworth, 1985).

Notes of Caution

One of the constraints on interpreting research on species diversity in oil palm is that there are few scientific case studies (Fitzherbert *et al.*, 2008). For example, there are no scientific studies that address plant diversity in oil palm. This introduces confounding factors that often cannot be controlled for. Research is required that addresses questions such as, what is the effect of area on species diversity when one compares species in a 50,000-ha natural forest with those in a 2500-ha oil-palm plantation? Would the species diversity of a 1000-ha oil-palm plantation be the same as a 10,000-ha one? What is the effect of fragmentation when areas of natural forests to which oil-palm diversity is compared are fragments themselves in a matrix of nonforests (Liow *et al.*, 2001)? How does species diversity vary in different oil-palm contexts, from the mixed-forest gardens settings often found in Africa to the large (>20,000-ha) monocultural plantings sometimes found in Indonesia?

Broader Environmental Impacts of Oil Palm

Oil Palm and Deforestation

Information on how much forest has been displaced by oil palm is hard to come by. Considering that oil palm is a crop of the humid tropics, one could argue that all planted oil palm has ultimately replaced tropical forest. Some forests, however, were cut down centuries ago and only recently planted with oil palm. Oil palm is developed under a wide range of field conditions, varying from old degraded grasslands, secondary scrubland, forest regrowth, degraded and overlogged forest, and relatively intact forests. In our experience, rarely has oil palm been established in areas that were primary forest (i.e., visually untouched by human activities) directly prior to oil-

palm development. Therefore, the more-pertinent question regarding oil palm and forest wildlife is how much forest has recently been cut down and directly been replaced by oil palm? A recent analysis of agricultural and deforestation statistics for the period 1990–2005 suggested that more than half the area of oil-palm developed in Malaysia and Indonesia had resulted in deforestation (Koh and Wilcove, 2008). Others, however, argue that the data are too poor to draw such conclusions and that these estimates do not account for other causes that triggered deforestation before oil-palm plantations were established (Wicke *et al.*, 2011).

To estimate future impacts, we need to know how much of the oil-palm expansion will be in forested areas. Future demand for edible oil is estimated at around 240 Mt in 2050, requiring an additional 12 million ha of palms, if average yields continue to rise as in the past (Corley, 2009). This demand could at least partly be met on existing nonforest lands (Wicke *et al.*, 2011). However, Corley (2009) also points out that biofuel demand might greatly exceed that for edible use, and the interchangeability of the major oils for edible and biofuel uses means that this demand will drive oil-palm expansion, whether or not palm oil is actually used for biodiesel.

Without a clear definition of oil palm-induced deforestation, better data on forest cover and the distribution of oil-palm plantations, and future expansion potential of oil palm, it remains impossible to accurately quantify the impact of oil-palm development on forest wildlife.

Some have argued that oil-palm plantations are forests. Malaysia, for example, has considered (but ultimately rejected) including oil-palm plantations in the country's national statistics on forest cover (Simamora, 2010). Many conservation bodies highlighted this as unacceptable (Biofuels Watch, 2010; World Rainforest Movement, 2010), and the Food and Agricultural Organization excludes oil palm from global forest estimates because it considers it an agricultural crop, not a planted forest (FAO, 2010). Meijaard and Sheil (2011) pointed out that in much of the temperate world pulpwood plantations are included as forests, and there is an obvious need to develop and agree on such definitions (Sasaki and Putz, 2009).

Broader Environmental Impacts of Oil-Palm Plantations

Palm-oil production has environmental impacts that could potentially affect wildlife beyond the actual plantation. Extraction of palm oil results in large amounts of effluent that is often returned to natural water courses without treatment (Sheil *et al.*, 2009). Palm-oil mill effluent is a colloidal suspension of water, oil, grease, and solids: it is fairly acidic (pH 4–5) and is typically discharged hot (80–90 °C) (Ahmad *et al.*, 2005). Although most mills have treatment areas, leaks of effluent can have significant negative impacts on water quality. How this affects the ecological functioning of waterways remains largely unstudied (Sheil *et al.*, 2009).

The oil-palm industry is one of the largest consumers of mineral fertilizers in Southeast Asia (Hardter and Fairhurst, 2003). A typical oil-palm plantation planted on both mineral and peat soils requires around 354 kg ha⁻¹ of nitrogen over the first 5 years to increase and maintain yields (Guyon and

Simorangkir, 2002). Pesticides and herbicides also increase pollution, especially with repeated use (Hartemink, 2005). Most of the reports on impacts are generated by companies and may not be objective because they wish to be seen as minimizing damage to the environment (Sheil *et al.*, 2009).

The environmental impact of oil-palm plantations could be less than most alternative crops if considered in terms of production – more can be produced on less land. Given the necessary trade-offs between conservation and economic growth, this is important. Better management, higher yields from improved varieties, and planting on land that is already degraded could improve yields significantly without further deforestation (Hardter *et al.*, 1997). Concentrating oil-producing crops on those lands with the highest yields could reduce the need for land elsewhere, offering potential conservation benefits.

Could Oil-Palm Development Reduce Biodiversity Impacts Elsewhere?

Large-scale oil-palm production has documented benefits. The plantation sector in Malaysia is one of the largest employers, providing income and employment for many rural people. Basiron (2007) comments that “involvement in cultivation or downstream activities has uplifted the quality of life of people.” Decreasing rural poverty may reduce deforestation, although this is highly context-specific (Sunderlin *et al.*, 2007; Wunder, 2001). Also, assuming a certain global demand for vegetable oil – for food and biofuel – producing it in areas with plant species that maximize yields could potentially reduce pressure on land elsewhere. The interactions between the various economic, trade, environment, and political factors remain too complex to reliably determine overall global impacts of oil palm on biodiversity compared to the alternative of producing oils with different crops. This is an important area of research to guide the different oil industries.

Enhancing the Biodiversity Values of Oil Palm

An important question regarding the biodiversity of oil-palm plantations is whether this can be boosted by retaining patches of natural forest within the oil-palm matrix, the so-called wildlife-friendly strategy (Edwards *et al.*, 2010; Fitzherbert *et al.*, 2008; Koh, 2008b). Oil palm developed in large estates can create monocultural stands of 50,000 ha or more. Such areas have very limited ecological variation and create large areas mostly devoid of wildlife. In a small-holder setting, oil palm is planted on much finer scales, often in plantations of 1 or 2 ha. If such plantations are part of a broader multifunctional landscape with remaining forest stands and secondary regrowth, the overall species diversity is likely to be higher. If a certain total area of oil-palm plantation is targeted to fulfill global demands, an important ecological question is whether for wildlife conservation purposes it is better to concentrate all oil palms into large monocultural stands (potentially leaving more space for natural forests) or to spread oil-palm plantings over much larger multifunctional landscapes.

A study comparing bird diversity in oil palm, forest fragments within oil palm, and contiguous natural forest indicated that abundances of imperiled bird species in oil palm were 60 times lower in fragments and 200 times lower in oil palm than in contiguous forest. Forest fragments did not increase bird abundances in adjacent oil palm, and they had lower species richness than contiguous forest and an avifaunal composition that was more similar to oil palm than to contiguous forest. The study concluded that, from a perspective of maximizing biodiversity conservation, any investment in the retention of fragments would be better directed toward the protection of contiguous forest (Edwards *et al.*, 2010) – that is, the land-sparing strategy.

Increasing the productivity of existing oil-palm plantations – for example, by better management of harvesting to improve oil yield – could potentially reduce the need for more land to be cleared. However, this will only generate a conservation gain if it is linked to the protection of natural habitats – for example, through strategic land-use planning and implementation (Fitzherbert *et al.*, 2008). Fitzherbert *et al.* (2008) argue that with higher yields per unit area for both large and small scale enterprises, oil palm might provide a substitute for traditional subsistence agriculture and could reduce the area of land needed to support each household. They also point out that successful land sparing is contingent on inelasticity of demand for agricultural products (Green *et al.*, 2005). The substitutability of vegetable oils ensures that demand for any one oil is elastic and, although future global requirements for edible oils – depending much on demand from China and India – may be reasonably predictable, demand will become effectively limitless if driven by new biofuel markets. Proposals for nongovernmental organizations to use oil-palm agriculture to acquire private reserves (Koh and Wilcove, 2007) are unlikely to be the most cost-effective approach (Venter *et al.*, 2008).

Meanwhile, several new international and national initiatives are under way to improve practices in establishing oil-palm plantations and using forests. One national initiative is Sawit Watch (*sawit* meaning oil palm), which campaigns for the rights of indigenous people in land disputes and highlights the social ramifications of oil-palm developments in Indonesia (Sheil *et al.*, 2009). International initiatives include the Roundtable for Sustainable Palm Oil (RSPO), which was established in 2004 by Malaysian and Indonesian companies to ensure palm oil “contributes to a better world.” The RSPO has developed a verifiable standard for sustainable palm oil and encourages oil-palm companies to adopt more-responsible practices. This standard consists of the RSPO Principles and Criteria (P&C) for Sustainable Palm Oil Production, which set out the requirements that must be met and against which certification assessments are made. To define sustainability in the oil-palm sector, the RSPO has developed 39 sustainability criteria organized under eight general principles that are designed to limit environmental impacts of growing and processing palm oil (Laurance *et al.*, 2010). Of these, principle four is of direct relevance to biodiversity. Among others, it requires that growers maintain soil fertility, minimize and control erosion and degradation of soils, maintain the quality and availability of surface and groundwater, regulate the use of agrochemicals, and effectively

manage pests, diseases, weeds, and invasive introduced species (RSPO, 2007). Most importantly for biodiversity in oil palm, however, is principle five, which concerns the environmental responsibility and conservation of natural resources and biodiversity. This focuses primarily on the design of plantations, most relevantly the clearing of natural vegetation and how this affects the status of rare, threatened, or endangered species and habitats of high conservation value. Specifically, if such species or habitats are present, the standard requires that any legal requirements relating to the protection of the species or habitat are met, damage to and deterioration of applicable habitats is avoided, and any illegal or inappropriate hunting, fishing, or collecting activities is controlled, including the development of responsible measures to resolve human-wildlife conflicts. Such conflicts are frequent – as has, for example, been indicated by the many reported cases of orangutan killing in association with oil-palm development (Meijaard *et al.*, 2011).

Despite its ambitious environmental goals, the RSPO has been criticized for failing to stop clearing of natural forests and, more generally, for noncompliance by its members (Laurance *et al.*, 2010). Also, many companies have experimented with the RSPO standard since it was ratified in November 2005 but have found it to be complicated, costly, and hard to implement (Nikoloyuk *et al.*, 2010; Paoli *et al.*, 2010). Recently, RSPO has channeled activities toward developing a standard for smallholders because they cannot afford the additional oversight required for mainstream RSPO certification. Smallholders also struggle to adopt best practices, such as zero burning, because such practices require up-front capital and are more expensive at the onset. It remains to be seen whether the lofty goal of “sustainable” palm-oil management can be attained through the RSPO process. Countries such as Indonesia that investigated ways of integrating RSPO principles into current policies (McCarthy and Zen, 2010) have apparently concluded that this was not possible and subsequently developed their own standards: the Indonesian Sustainable Palm Oil Foundation (ISPO).

Conclusions

The scientific evidence suggests that oil-palm plantations in equatorial Asia have low biodiversity value compared to most other tropical land uses. A few species do well in oil palm, but these generally have little conservation value. Species that lose out in oil palm are forest-dependent species with specific habitat requirements and low abundance, and many are of conservation significance (Persey, 2011).

It is possible to make the oil-palm industry more biodiversity-friendly. It is most important, however, that oil palm should be developed on already deforested or degraded lands rather than in areas of tropical forest. Oil palm itself can also be made more hospitable for biodiversity – for example, by increasing structural and faunistic diversity (e.g., allowing the growth of epiphytic ferns and maintaining weed cover) and retaining as much natural forest in and around the planted areas as possible.

Ultimately, the global impact of oil palm on biodiversity can only be judged in relation to the alternatives. There is an

increasing demand for vegetable oils for food and other uses, and demand for biofuels is growing. Oils and biofuels can be generated with different crops, and oil palm has the highest yield per unit land area and per unit of financial investments. If oil palm is not expanded further, then either the demand for oil will not be met or it will be fulfilled with other crops that require more land than would the oil palm.

Glossary

Bushmeat Wildlife such as primates not traditionally considered edible that is hunted and used for food, usually illegally.

Diversity The variety of species within a given taxonomic group.

Endemic A species or taxonomic group unique to or occurring only in a specified geographic location or region.

Flagship A popular, charismatic species that serves as a symbol and rallying point to stimulate conservation awareness and action.

Haplorrhini One of the two recognized primate suborders; includes the tarsiers, New World monkeys, Old World monkeys, and apes.

Megadiversity countries Countries which harbor a disproportionately large share of the world's fauna. In terms of primates, the four megadiversity countries are Brazil,

Madagascar, the Democratic Republic of Congo, and Indonesia.

Prosimians A rather scientifically imprecise grouping that includes such "Lower" primates such as galagos, lorises, lemurs, and tarsiers.

Strepsirrhini The other of two recognized primate suborders; includes the galagos, lorises, and lemurs.

Zoogeographical regions One of six geographical divisions of the world devised for the study of the distribution of land mammals. They consist of the Palearctic, the Nearctic (North America), the Neotropical (South America), the Afrotropical (Africa south of the Sahara), the Oriental (Asia south of the Himalayas), and the Australasian (Australia, New Zealand and nearby islands), the latter two featuring a zone of overlap known as Wallacea. Antarctica forms an additional region.

Introduction

During the past few decades, interest in nonhuman primates has increased significantly on many fronts and has helped to build support for conservation. Pioneering and long-term field studies of the great apes (Schaller, 1963; Goodall, 1968; Fossey, 1983; Galdikas, 1995) have dispelled age-old myths about mankind's closest living relatives, greatly narrowing the gaps between these species and our own, and provided new insights into human origins and behavior. The continuing search for new drugs to treat global maladies such as malaria, cancer, and AIDS has required large numbers of nonhuman primates as experimental subjects (Mack and Mittermeier, 1984). For some species, this use has contributed to serious declines in wild populations and ultimately forced issues of conservation and captive breeding as part of the long-term strategy for biomedical research. In other cases, little-known and formerly obscure primate species of the Neotropics, Africa, and Asia have emerged as prominent "flagships" for conserving their tropical forest habitats, which biologists agree are the richest natural terrestrial ecosystems on the planet.

Although interest in nonhuman primates is increasing, the threats to their survival persist. Varying combinations of habitat destruction, hunting, and live capture have driven dozens of primate species and subspecies to the brink of extinction, to the point where several taxa now number only in the low thousands or hundreds, and for some species less than a hundred now remain. Such populations are doomed without long-term protection, monitoring, and a heightened understanding of their plight by local human populations.

In the face of continuing threats, however, primate conservationists can also reflect on the past century and realize with some degree of pride that, to the best of anyone's knowledge, not a single primate taxon went extinct during that period. Certainly it is true that, during the first decade of this new century, at least two primates have been feared lost: Miss Waldron's red colobus (*Piliocolobus waldronae*) and the Yunnan white-handed gibbon (*Hylobates lar yunnanensis*). However, in the case of the former, at least there remains some reasonable hope that it may yet survive, while the latter is still officially considered Data Deficient by the International Union for Conservation of Nature and Natural Resources (IUCN). The near future could conceivably witness the loss of many others, as for instance the Hainan gibbon (*Nomascus hainanus*) of China, the Tonkin snub-nosed monkey (*Rhinopithecus avunculus*) of Vietnam or the Sahafary sportive lemur (*Lepilemur septentrionalis*) of Madagascar, all Critically Endangered. The survival of these and other threatened taxa will depend on the continuation of existing conservation programs, and the establishment of new ones according to a global strategy for the most threatened. Fortunately, support for global primate conservation increased in the latter half of the 1990s after having suffered something of a dry spell, and the expertise is at hand to direct available resources to the highest priority species, habitats, and projects.

Overview of Global Primate Diversity and Conservation

The order Primates is one of 29 mammalian orders that together total more than 5500 species. It includes 16 families,

78 genera, and at last count, 438 species and 673 taxa worldwide. Two suborders of primates are recognized, the Strepsirrhini (galagos, lorises, and lemurs) with seven families, and the Haplorrhini (tarsiers, New World monkeys, Old World Monkeys, and apes) with nine (Table 1).

Living strepsirrhines occur only in the Old World, despite the fact that North America was once a major center of their early evolutionary history. Of the seven extant strepsirrhine families, five (Cheirogaleidae, Lepilemuridae, Lemuridae, Indriidae, and Daubentoniidae) occur naturally only in Madagascar, where they are represented by 15 genera, 97 species, and 101 taxa. The five genera, 19 species, and 30 taxa of the Galagidae are confined to sub-Saharan Africa, while the four genera, 12 species, and 17 taxa of the Lorisidae are found in mainland Africa, India, and Southeast Asia.

The haplorhine primates are much more diverse than the strepsirrhines, having three times the number of genera and three-and-a-half times the number of species and total taxa. Of the nine haplorhine families, five (Callitrichidae, Cebidae, Aotidae, Pitheciidae, and Atelidae) occur only in the New World tropics, two (Cercopithecidae and Hominidae) occur throughout much of Africa and Asia, and two (Hylobatidae and Tarsiidae) are restricted to Asia. The family Tarsiidae is currently represented in Indonesia and the Philippines by three genera, 11 species, and 16 taxa; however, a major taxonomic revision of the group is now underway, which is expected to significantly increase these numbers. New World nonhuman primates comprise 20 genera, 148 species, and 204 taxa. By comparison, the Old World monkeys (subfamilies

Colobinae and Cercopithecinae), although much more widely distributed, are only somewhat more diverse, comprising 23 genera, 125 species, and 264 taxa overall. The gibbons (Hylobatidae) are a relatively small group that includes four genera, 17 species, and 27 taxa, while the great apes (Hominidae) are even less diverse with four genera, seven species, and only 14 taxa overall. It should be noted that the human primate is considered a morphologically variable but monotypic member of the latter family. For the remainder of this article, the authors use "primate" only in reference to non-human taxa unless otherwise specified.

Examining global primate diversity from a regional perspective, it can be seen that it is by no means evenly distributed. For example, the remaining tropical forests of Madagascar are dwarfed by the extensive tropical forests of Africa, Asia, and Central and South America, but Madagascar has by far the densest concentration of primate diversity anywhere on Earth within an area of 587,045 km². Although usually considered part of the Afrotropic zoogeographical region, Madagascar is in many respects a zoogeographic region by itself, and especially so with respect to its unique primate fauna. All of Madagascar's primates are endemic, with the exception of the mongoose lemur (*Eulemur mongoz*) and the brown lemur (*Eulemur fulvus*), which also occur on the nearby Comoros Islands but were almost certainly introduced there by humans.

With the exception of the Barbary macaque (*Macaca sylvanus*), all primates of sub-Saharan Africa and nearby islands (e.g., Zanzibar and Bioko) occur within the Afrotropic zoogeographical region. They include 25 genera, 101 species, and

Table 1 Primate diversity by family

Family	Common names	Distribution	Genera	Species	Taxa
<i>Suborder Strepsirrhini</i>					
Galagidae	Dwarf galagos, lesser galagos, squirrel galagos, needle-clawed galagos, and thick-tailed galagos	Africa	5	19	30
Lorisidae	Slender lorises, slow lorises, angwantibos, and pottos	Asia, Africa	4	12	17
Cheirogaleidae	Mouse lemurs, giant mouse lemurs, hairy-eared mouse lemur, dwarf lemurs, and fork-marked lemurs	Madagascar	5	30	30
Lepilemuridae	Sportive lemurs	Madagascar	1	26	26
Lemuridae	Bamboo lemurs, ring-tailed lemur, true lemurs, and ruffed lemurs	Madagascar	5	23	25
Indriidae	Woolly lemurs, sifakas, simponas, and indri	Madagascar	3	19	19
Daubentoniidae	Aye-aye	Madagascar	1	1	1
<i>Total Strepsirrhini</i>			24	130	148
<i>Suborder Haplorrhini</i>					
Tarsiidae	Tarsiers	Asia	3	11	16
Callitrichidae	Marmosets, Goeldi's monkey, tamarins, and lion tamarins	Neotropics	7	43	62
Cebidae	Squirrel monkeys and capuchin monkeys	Neotropics	3	22	36
Aotidae	Night monkeys	Neotropics	1	11	13
Pitheciidae	Titi monkeys, sakis, bearded sakis, and uakaris	Neotropics	4	44	51
Atelidae	Howler, woolly monkeys, spider monkeys, and muriquis	Neotropics	5	28	42
Cercopithecidae	Guenons, macaques, crested mangabeys, baboons, drills, white-eyelid mangabeys, kipunji, colobus monkeys, langurs, surilis, and odd-nosed monkeys	Africa, Asia	23	125	264
Hylobatidae	Gibbons and siamang	Asia	4	17	27
Hominidae	Orangutans, gorillas, chimpanzees, and humans	Africa, Asia	4	7	14
<i>Total Haplorrhini</i>			54	308	525
<i>Total</i>			78	438	673

177 taxa overall. If we consider Madagascar in combination with the African continent, the entire region harbors a significant 45% of global primate diversity at the species level, and an even more impressive 52% of higher order (beta) diversity at the generic level.

In the Neotropics, primates occur from southern Mexico through Central America and northern South America and as far as southern Brazil, northern Argentina, and Paraguay (but not Chile). Native primate populations also occur in Trinidad; there are several introduced populations of African primates on the islands of St Kitts, Nevis, Barbados, and Grenada; and both New World and Old World species have been introduced to the island of Puerto Rico. Twenty genera and 204 taxa are found in the Neotropics – amounts roughly comparable to those for Africa and Asia. However, the 148 primate species of the Neotropics are the most for any single major region, and account for 34% of global primate diversity.

Asian primates are found mainly in the Oriental zoogeographical region and in the southeastern portion of the Palearctic, as well as in the Wallacea transition zone between the Oriental and Australian regions. In southern Asia, primates are widely distributed from the Indian subcontinent and the island of Sri Lanka, throughout Southeast Asia as far as the Philippines and the Indonesian islands of Halmahera and Sulawesi, to Central and North Asia from Afghanistan through southern China (including the islands of Hainan and Taiwan) to Japan. In contrast to Africa (excluding Madagascar) and the Neotropics, where primates are basically continental, Asian primates are found in large numbers on islands as well. The region is home to 18 genera, 91 species, and 190 taxa, a somewhat lower level of generic diversity by comparison to the Neotropics and Africa but a level of species diversity roughly equal to that of Africa.

Ninety-one of the world's 193 sovereign nations have wild primate populations; the 10 countries with the highest primate diversity are listed in Table 2. Brazil, with 114 species, is the leader and accounts for 77% of all Neotropical primate species. Together, the top four countries (Brazil, Madagascar, Indonesia, and Democratic Republic of the Congo), which also represent the world's four major primate habitat regions, account for 301 species and 387 taxa, or nearly 60% of all living primates.

Furthermore, the top four countries for primate diversity (Brazil, Madagascar, Indonesia, and Democratic Republic of Congo) are also at the top of the list of the world's top

countries for primate endemism (Table 3). Madagascar is by far the international superstar with 97 unique species, 15 unique genera, and five unique families, all representing 100% levels of endemism.

Endemic primates in Brazil and Indonesia account for approximately 58% and 72% of the species and subspecies that occur there. Brazil has fewer endemic species (71) than does Madagascar, despite the fact that it covers an area almost 15 times as large, and only four (*Callibella*, *Callithrix*, *Leontopithecus*, and *Brachyteles*) of its 19 primate genera (21%) are endemic. Indonesia is a distant third on the list with 28 endemic species and one endemic genus (*Simias*), after which the number of endemic species decreases precipitously. Only three other countries in the world – Tanzania (*Rungwecebus*), Peru (*Oreonax*), and Ethiopia (*Theropithecus*) – can claim an endemic primate species.

The key point is that there are a handful of countries, within the broad geographic regions that provide critical habitat for wild populations of nonhuman primates, which harbor a disproportionately large share of the world's primate fauna. The four megadiversity countries – Madagascar, Brazil, Indonesia, and Democratic Republic of the Congo – must therefore rank as the highest global priorities for conserving primates. Furthermore, if we extend the analysis to consider subspecies, we find that other countries will rise to the top of the priority list. Consider India for example. With 22 primate species and six endemics, it is well behind many other countries on the previous lists. However, of India's 31 primate taxa, 11 are endemic, and the additional six endemic subspecies represent important wild populations that should be considered when establishing conservation priority rankings.

Threats to Primates

Man-made threats to the survival of nonhuman primates can be divided into three major categories: habitat destruction (elimination, degradation, and fragmentation), hunting for food and a variety of other purposes, and capture for export or local trade (living, dead, and body parts) (Mittermeier *et al.*, 1986; Nijman, 2005). The effects of these vary significantly from species to species and from region to region, and are influenced by the extent and distribution pattern of remaining habitat, human population densities, the presence of roads and large rivers, the nature, and degree of human activities in

Table 2 World's top 10 countries for primate diversity

Country	Genera	Species	Taxa
Brazil	19	114	135
Madagascar	15	97	101
Indonesia	10	47	77
Democratic Republic of Congo	17	45	70
Peru	14	37	51
Colombia	13	40	51
Tanzania	13	26	46
Cameroon	20	34	44
Kenya	11	20	39
Uganda	15	24	37

Table 3 World's top 10 countries for primate endemism

Country	Genus	Species	Taxa
Madagascar	15	97	101
Brazil	4	71	78
Indonesia	1	29	56
Colombia	0	8	17
Democratic Republic of Congo	0	9	16
China (including Taiwan)	0	5	13
Tanzania	1	6	11
India	0	6	11
Sri Lanka	0	3	11
Kenya	0	3	9

the range of a particular species, local hunting traditions, the size and desirability of different species as food items or as sources of other products valued by humans, the demand for a given species in research or the pet trade, enforcement of existing wildlife laws, and regulation of commercial animal dealers. However, one or more of the three major threats affect almost all primates. It should be noted that, in addition to man-made threats, there are also certain other natural ones that can seriously impact populations. These include stochastic events such as cyclones, which have the potential to destroy large areas of habitat, and pandemics such as Ebola, which in recent years have decimated great ape numbers in Central Africa.

Habitat Destruction

On a global scale, habitat destruction is the principal factor contributing to the disappearance of wild primate populations. The continuing growth of the human population and its ever-expanding need for natural resources have contributed greatly to the destruction or alteration of natural habitats on an almost unimaginable magnitude, and nowhere has this problem been more acute than in the tropical regions of the world. The overwhelming majority of all nonhuman primates inhabit the tropical forests of Africa, Asia, and South and Central America. Although there are signs that the rate of destruction has been slowing somewhat since the 1990s, these forests are still being cut at an alarming rate. Just as troubling is the situation in Madagascar, which had become something of a conservation success story after years of rampant deforestation but, in the wake of recent political discord, is now suffering from a resurgence of burning, logging, and hunting, and where certain national parks are now being looted for their valuable hardwoods.

The immediate effects of habitat destruction on nonhuman primates vary significantly from one region to the next. For example, in Madagascar and the Atlantic forest region of eastern Brazil, so little suitable forest habitat remains that any further loss constitutes a grave threat to primates and other wildlife. In contrast, in the vast forest regions of Amazonia and the Congo Basin, which, along with the island of New Guinea, represent the three remaining major tropical wilderness areas of the planet, the effects of habitat destruction are only starting to be felt.

Hunting for Food and Other Purposes

The hunting of primates by human populations occurs for a variety of reasons, but by far the most important is to acquire food. Although primate hunting is prohibited by law in most countries, enforcement of such protective legislation is typically rare and sometimes nonexistent in the remote areas where this activity almost always occurs.

Hunting of primates as a source of food is a significant threat in at least three parts of the world: West Africa, Central Africa, and the Amazon region of South America. In each region, primates are among the animals most frequently hunted and they are regularly sold in markets, except where this is prohibited by law. However, even in areas in which primate

hunting is common, it by no means affects all species equally. In Amazonia, for example, the larger monkeys such as *Cebus*, *Lagothrix*, *Alouatta*, and *Ateles* are heavily hunted because they are among the most desirable food species, whereas smaller monkeys such as *Saguinus* and *Saimiri* are rarely shot for food because they barely provide enough meat to recompense the hunter for the cost of his or her shotgun shell. As a result of better law enforcement in recent decades in countries such as Brazil, "bushmeat" hunting is no longer considered a serious threat to wild primate populations. The situation in Central and West Africa, in contrast, has quickly reached a critical stage because bushmeat hunters in these regions are being paid by logging companies to shoot large quantities of primates and other forest wildlife to feed work crews.

In areas where the hunting of primates for food is common, it can sometimes comprise a threat even more severe than forest destruction. In some parts of Amazonia there are large tracts of primary forest remaining in which populations of *Cebus*, *Alouatta*, *Lagothrix*, and *Ateles* have effectively been exterminated by excessive hunting (Mittermeier and Coimbra-Filho, 1977; Peres, 2000). This is sometimes referred to as the "empty forest syndrome" (Redford, 1992), and is particularly evident in Central and West Africa, where widespread hunting for the bushmeat trade (as opposed to subsistence) is devastating monkey and ape populations (Ammann, 2000). In areas where food hunting and deforestation are both prevalent, populations of forest primates and other game species can disappear quickly.

In some parts of the world, religious restrictions or other cultural factors prohibit (or inhibit) the killing and eating of primates. In many parts of India, for example, primates are rarely hunted for food because they are linked to the monkey god Hanuman, of the Hindu religion, whereas in strictly Muslim countries primates are not eaten because their flesh is considered unclean and unfit for human consumption. Indeed, in India, Hindus refuse to kill rhesus macaques (*Macaca mulatta*) and resist translocating them even when populations become so high that they constitute a menace to humans. In other countries, such as Madagascar, local taboos may exist against eating certain primates (e.g., *Indri*), whereas other species (e.g., *Eulemur* and *Varecia*) may be the most popular food items for a given tribe or village. Sadly, in recent years such taboos have begun to break down, with the result that hunting has begun to seriously impact many species that were formerly protected in this way.

Primates are also hunted to supply many other products in addition to food: traditional medicines, bait, body parts for ornamentation, and trophies. Primate hunting to provide medicinal products may be nothing more than a by-product of food hunting in most cases, and it usually involves the use of specific body parts for their supposed medicinal value. Illegal and unsustainable trade in wildlife, in particular primates, is a major conservation challenge in Asia. Trade in primates for body parts and tissues for traditional medicine, folklore, and food is particularly prevalent, cruel and enormously detrimental to populations of numerous Asian primates (Nekaris *et al.*, 2010). Trade in lorises (*Loris* and especially *Nycticebus*), for instance, is resulting in fast-declining populations and local extinctions (Nekaris and Nijman, 2007; Nekaris *et al.*, 2010). In south India, the meat of the Nilgiri

langur (*Trachypithecus johnii*) and the lion-tailed macaque (*Macaca silenus*) is regarded as an aphrodisiac and thought by local people to contain other therapeutic properties. The blood of Asian colobine monkeys, such as Phayre's langur (*Trachypithecus phayrei*) in Thailand, is widely believed to impart vigor to the drinker, especially when mixed with local whisky. So too, in various South American countries, drinking from the cup-shaped hyoid of an adult male howler monkey (*Alouatta*) is thought to cure goiters and stuttering as well as ease a mother's labor pains during childbirth. Although the hunting of primates for supposed medicinal purposes is considered a relatively minor factor overall in the global decline of wild primate populations, when it involves threatened species, such as in the case of India's lion-tailed macaque or some of the Southeast Asian colobines (*Trachypithecus*, *Presbytis*, and *Pygathrix*), it can be a serious problem.

Primates are also shot to provide bait for capturing and killing other animals, mainly in remote areas of the Amazon region. There, spotted cat hunters preferentially shoot larger monkeys such as *Lagothrix* and *Ateles* to bait crude wooden traps set for jaguars and ocelots. Any number of Amazonian primates may also be shot for fish or turtle bait, and in Sri Lanka monkeys often serve as bait for crocodiles. Although the use of primates for bait is a relatively minor threat, it can and does add to the pressures faced by overexploited large taxa such as *Lagothrix* and *Ateles*.

In some countries, primates may be killed for their skins or to provide other body parts used in ornamentation. Perhaps the most striking case of this is in Africa, where the skins of guereza (*Colobus guereza*) and related species have been used to fashion cloaks and headdresses for native African peoples, but have also figured significantly in the international fur trade. For example, in 1899 a reported 223,599 monkey skins were auctioned in London, and at least 2.5 million were probably exported to Europe between 1880 and 1900, especially to Germany, where they were used to make capes, muffs, and rugs. As recently as the early 1970s, colobus monkey rugs were common in East African tourist shops, and colobus coats were being sold in Europe and Japan.

Throughout much of Amazonia, tourist shops still offer stuffed monkeys, monkey skulls, monkey-skin hats, monkey-tail dusters, and necklaces fashioned from monkey teeth, bones, hands, feet, and tails. However, these products are typically available on a small scale, and almost always as a by-product of hunting for food.

Nonetheless, the demand for primate body parts for sale to tourists can be a serious matter if it involves threatened species. The most striking example of this was the slaughter of mountain gorillas (*Gorilla beringei beringei*) in Rwanda and the Democratic Republic of Congo, in order to provide hands and skulls for sale to European tourists (Fossey, 1983). Although rare, this practice still occurs on occasion despite effective, long-term conservation programs in this region.

Hunting primates for sport is fortunately rare and a minor threat to wild populations. It appears to be most prevalent near logging camps and within military zones in remote areas of developing countries, where arms are plentiful and law enforcement is basically nonexistent. Children armed with slingshots and air rifles are often among the worst offenders. More prestigious trophy hunting has also played a role

(albeit a minor one) in primate decline. Species such as gorilla were especially desirable quarry for nineteenth-century and early twentieth-century trophy hunters, and the tales of their exploits are recounted in many books. On the whole, however, sport hunting must be considered a very minor factor unless a threatened species is involved, in which case the activity is almost always illegal as well.

A final reason for hunting primates considered here is because they are sometimes considered agricultural pests; for some African and Asian species, this can represent a significant drain on wild populations. The most striking example is that of government-sponsored "monkey-drives" that were common in Sierra Leone several decades ago. Eleven of the country's 15 primate species were routinely shot or driven into nets and clubbed to death during such drives; only three species were considered harmless to farm crops. According to government records, approximately 250,000 monkeys were destroyed in such drives between 1949 and 1952, and these were only the ones actually counted. Bounties were paid for primate heads or tails, and there was no control over the species killed.

The major crop-raiders are usually the more adaptable and widespread species, such as the savanna-dwelling baboons (*Papio*) in Africa and the macaques (*Macaca* spp.) in Asia, but there are also instances of orangutans (*Pongo* spp.) being killed for raiding fruit trees and gorillas (*Gorilla*) being killed for destroying crops. The only Neotropical species regarded as agricultural pests are the capuchins (*Cebus* and *Sapajus*), whose common names sometimes reflect their crop-raiding habits. For example, the common name for the large-headed capuchin (*Cebus macrocephalus*) in Colombia is *maicero* and one of the Surinamese names for the weeper capuchin (*Cebus olivaceus*) is *nyan-karu mongi*, both of which translate as "corn-eater."

It is difficult to assess how much damage primates actually do to crops in different parts of the world. It is equally difficult to determine how effective pest control efforts have been or to what degree they have contributed to the decline of wild primate populations. However, as primate habitats continue to be encroached on, resulting in shortages of other food sources, it is likely that the more adaptable primate species will continue to raid crops and perhaps become more dependent on them as a food source. This, unfortunately, will likely result in an increased conflict between man and nonhuman primates.

Live Capture of Primates

Primates have routinely been captured alive for export (the international trade to supply zoos and for biomedical research and pharmaceutical testing) or to serve local pet trades. The height of the international primate trade began at the end of the 1950s and continued through the early 1960s, during which time hundreds of thousands of monkeys were taken from the wild each year (Mack and Mittermeier, 1984). The trade consisted largely of rhesus macaques (*M. mulatta*), exported from India and used in laboratory tests as part of the effort to develop a vaccine for polio, and squirrel monkeys (*Saimiri*) imported by the United States from several

Amazonian countries. Subsequently, the imposition of export bans by habitat countries, import restrictions by user countries, and a decreased demand from biomedical research and zoological parks contributed to a significant decline in the international traffic in primates. Currently, the capture and exploitation of long-tailed macaques (*Macaca fascicularis*) from Indochinese countries is of particular concern in this respect.

In 1982, in recognition of the serious effect that live capture for export can have on wild primate populations, the IUCN Species Survival Commission (SSC) Primate Specialist Group (PSG) prepared a *Policy Statement on the Use of Primates for Biomedical Purposes*. The latter included the recommendation that the most threatened species be considered for use in biomedical research projects only if they are obtained from existing, self-sustaining captive breeding colonies. This policy statement was subsequently adopted by the World Health Organization and the Ecosystem Conservation Group of the United Nations, which includes UNESCO, the Food and Agricultural Organization (FAO), UNEP, and IUCN. It is still valid today.

Conservation Status of Primates

The IUCN Red List of Threatened Species provides a regularly updated, comprehensive status assessment of the world's primates. All primate taxa have been identified in this assessment as Extinct, Extinct in the Wild, Threatened (including three categories Critically Endangered, Endangered, and Vulnerable), Near Threatened, Least Concern, Data Deficient, or Not Evaluated. A taxon is defined as:

1. *Critically Endangered* if the rate of population reduction is estimated to be greater than 80% for more than 10 years or three generations, if the extent of its occurrence is estimated to be less than 100 km², if its population is estimated to be less than 250 individuals, and quantitative analysis indicates the probability of extinction in the wild is at least 50% within 10 years or three generations.
2. *Endangered* if the rate of population reduction is estimated to be greater than 50% for more than 10 years or three generations, if the extent of its occurrence is estimated to be less than 5000 km², if its population is estimated to number less than 2500 individuals, and if quantitative analysis shows the probability of extinction in the wild is at least 20% within 20 years or five generations.
3. *Vulnerable* if the rate of population reduction is estimated to be greater than 30% for more than 10 years or three generations, if the extent of its occurrence is estimated to be less than 20,000 km², if its population is estimated to number less than 10,000 individuals, and if quantitative analysis shows the probability of extinction in the wild is at least 10% within 100 years.

As a result of this assessment, 309 (46%) of the world's 672 primate taxa are considered Critically Endangered, Endangered, or Vulnerable. Of these, 204 taxa (30%) are listed as Critically Endangered or Endangered – 49 in the Neotropics, 42 in Africa, 26 in Madagascar, and 87 in Asia (Table 4 and Table 5).

At least 23 genera (*Nycticebus*, *Hapalemur*, *Prolemur*, *Varecia*, *Propithecus*, *Indri*, *Callibella*, *Leontopithecus*, *Oreonax*, *Brachyteles*, *Nasalis*, *Simias*, *Rhinopithecus*, *Pygathrix*, *Allochrocebus*, *Mandrillus*, *Rungwecebus*, *Hoolock*, *Nomascus*, *Symphalangus*, *Pongo*, *Gorilla*, and *Pan*) are considered threatened.

Primate Conservation in the New Millennium

The IUCN was established in 1948 to promote and carry out scientifically based action for the conservation and sustainable use of living natural resources. IUCN enrolls sovereign states, governmental agencies, research institutions, and nongovernmental organizations to conserve the world's natural heritage. The SSC was founded in 1949 and is the largest of the IUCN's six commissions, with some 8000 volunteer member scientists, field researchers, government officials, and conservation leaders from almost every country in the world. SSC works principally through its more than 120 specialist groups and Task Forces, of which the PSG is one of the largest. There is a section of about 115 members which deals specifically with great apes, and an additional nine sections for regions in which primates occur (West, Central and East Africa, Madagascar, the Andes, Mesoamerica, Brazil and the Guianas, South Asia, Southeast Asia, and China), each of them with at least one regional coordinator. The total number of members exceeds 400.

The founding mission of the PSG is to maintain the current diversity of the order Primates, with dual emphasis on (1) ensuring the survival of Critically Endangered, Endangered, and Vulnerable species wherever they occur, and (2) providing effective protection for large numbers of primates in areas of high primate diversity and abundance. Much of the work of the PSG over the past few decades has been made possible by Conservation International, an Arlington, VA-based NGO which has housed the Chair and the Deputy Chair over that period and has provided and facilitated many activities on behalf of primates. These include those mentioned above, and also large-scale protection of many areas of primate rainforest habitat through the Global Conservation Fund, the Critical Ecosystem Partnership Fund, and the Centers for Biodiversity Conservation in South America and Madagascar. Other key institutions that contributed significantly to primate conservation during this period included the New York Zoological Society (now Wildlife Conservation Society), the Fauna and Flora Preservation Society (now Fauna & Flora International), the Jersey Wildlife Preservation Trust (now Durrell Wildlife Conservation Trust), Wildlife Preservation Trust International (now EcoHealth Alliance), and the National Geographic Society.

In late 1977, the chairman of the PSG, in collaboration with group members, wrote *Global Strategy for Primate Conservation* (Mittermeier, 1978). This document was an attempt to organize primate conservation activities based on the highest international priorities, and to ensure that limited funds available for primate conservation were put to the best possible use. The first draft of the *Global Strategy* included 65 projects in Africa, Asia, and South and Central America. Each project was categorized as highest priority, high priority, priority, and desirable based mainly on the status of the focal

Table 4 Critically Endangered and Endangered primates

Critically Endangered	Endangered
Rondo dwarf galago (<i>Galagoides rondoensis</i>)	Zanzibar dwarf galago (<i>Galagoides zanzibaricus zanzibaricus</i>)
Sahafary sportive lemur (<i>Lepilemur septentrionalis</i>)	Bioko squirrel galago (<i>Sciurocheirus alleni alleni</i>)
Lac Alaotra bamboo lemur (<i>Hapalemur alaotrensis</i>)	Bioko needle-clawed galago (<i>Euoticus pallidus pallidus</i>)
Greater bamboo lemur (<i>Prolemur simus</i>)	Lowland red slender loris (<i>Loris tardigradus tardigradus</i>)
Variiegated black-and-white ruffed Lemur (<i>Varecia variegata variegata</i>)	Horton Plains red slender loris (<i>Loris tardigradus nycticeboides</i>)
Southern black-and-white ruffed Lemur (<i>Varecia variegata editorum</i>)	Highland gray slender loris (<i>Loris lydekkerianus grandis</i>)
Northern black-and-white ruffed Lemur (<i>Varecia variegata subcincta</i>)	Northern gray slender loris (<i>Loris lydekkerianus nordicus</i>)

Table 5 Threatened primates by region

Region	Taxa	Threatened (%)	Critically Endangered (%)	Endangered (%)
Asia	182	124 (68%)	26 (14%)	61 (34%)
Madagascar	101	40 (40%)	8 (8%)	18 (18%)
Neotropics	201	79 (39%)	23 (11%)	26 (13%)
Africa	186	66 (35%)	12 (6%)	30 (21%)

species and how likely the project would be to bring about the desired conservation action. The *Global Strategy* quickly resulted in a substantial increase in funding for primate conservation activities, and in 1979 it led to the establishment of a special Primate Program and Primate Action Fund by the World Wildlife Fund-US. In addition to major endeavors supported as a result of this program, the Primate Action Fund provided rapid support for small primate conservation projects, workshops, and relevant events (ranging from \$500 to \$5000). It has now functioned for more than 30 years, contributing, in the process, several million dollars to hundreds of worthy projects.

Almost a decade after the *Global Strategy* was launched, the first regional primate conservation action plans were prepared by the IUCN/SSC PSG. First to be published was the *Action Plan for African Primate Conservation: 1986–1990* (Oates, 1986), which was quickly followed by the *Action Plan for Asian Primate Conservation: 1987–1991* (Eudey, 1987), and several years later by *Lemurs of Madagascar, An Action Plan for Their Conservation: 1993–1999* (Mittermeier *et al.*, 1992) and by *African Primates: Status Survey and Conservation Action Plan* (Oates, 1996), the latter being an update of the 1986 document. The PSG has also produced regional action plans, shorter publications which put primate conservation into a comprehensive regional perspective: among these are *Chimpanzees in West Africa* (Kormos *et al.*, 2003), *Chimpanzees and Gorillas in Western Equatorial Africa* (Tutin *et al.*, 2005), *Sumatran Orangutan Conservation Action Plan* (Ellis *et al.*, 2006), and *Regional Action Plan for the Conservation of the Cross River Gorilla* (Oates *et al.*, 2007). Together, these action plans have effectively focused conservation activities in three or four

major regions in which primates occur, and served as useful measures with regard to the success of proposed strategies.

The first vehicle for regular and effective communication among the world's primate conservationists was the IUCN/SSC *Primate Specialist Group Newsletter*, which was launched in 1981. Changed to *Primate Conservation* in 1985, it has gradually evolved into a journal that continues to be published annually. In addition, the four regional sections of the PSG subsequently began publishing their own periodic newsletters to meet the increasing need for more timely information. *Asian Primates* appeared in 1991 and was published until 2002; after a lengthy hiatus, it has recently been replaced by an annual *Asian Primates* journal. *African Primates* debuted in 1995 and has had a similar history, having been relaunched in 2010 as a yearly journal. *Neotropical Primates* and *Lemur News* appeared in 1993, and are both still published regularly as journals. Taken in combination, these periodicals have significantly increased the amount, quantity, and timeliness of information available to primate conservationists throughout the world. Other important aspects of the PSG involve the organization of workshops and meetings, in order to discuss program activities in addition to aspects such as taxonomy and the regional coordination of conservation measures. The group also maintains databases and a website that serves as a valuable resource for members, researchers and the public alike, providing information on primate diversity, threat status, and current conservation efforts. A general media outreach on the importance of primate conservation, to ensure that it remains regularly in the news, is also a major priority. Last but not least, there is the continual search for additional resources to fund primate conservation in the field.

Outlook for the Future

In the future, there is a need to sustain conservation activities based on recommendations of the original *Global Strategy for Primate Conservation* and subsequent publications, as well as to increase the focus on those primate taxa deemed closest to extinction. The twentieth century ended without a single primate taxon having been lost – an enviable record indeed considering the number of reptiles, birds, and other mammals known to have disappeared during this period. However, at least one form has already been officially declared extinct in the new millennium, and many more species and subspecies are in serious jeopardy. Much of the groundwork for developing a more focused conservation strategy has already been done. The *IUCN Red List of Threatened Animals* provides a good starting point for identifying the highest priority taxa. To those that are considered Critically Endangered and Endangered, we expect that the PSG will continue to add more species and subspecies, while at the same time considering factors such as taxonomic uniqueness in order to establish priority rankings for conservation action. The results of much of this analysis are nowadays presented in *The World's 25 Most Endangered Primates*, a biennial publication that serves to draw attention to the most critically threatened forms. This synthesis and publication of information is vital for fomenting and stimulating measures for the conservation of primates and their forests worldwide.

In addition to the above activities, there are also other important priorities that need to be maintained in the coming years. These include an increase in primate-focused ecotourism, coupled with the training of nationals from primate habitat countries, the latter by way of the provision of small- to medium-sized grants for primate research and primate conservation measures in the field. New national parks and reserves need to be set aside for threatened species as well as in areas of high primate diversity and abundance, and those that already exist need to be strengthened in terms of their infrastructure as well as in the enforcement of protective legislation within them. On a broader scale, there is a need to determine ways in which humans and nonhuman primates can coexist better in multiple-use areas. Zoos must also continue to do their part, mainly by establishing conservation-oriented captive breeding programs for threatened taxa and by helping to end the illegal and otherwise destructive traffic in primates. Those research institutions using primates need to be made more aware of conservation issues and the status of the species that they use, ensure that they use primates as prudently as possible, and make every attempt to breed most or all of the primates that they require. Perhaps most important of all, public awareness needs to be created regarding the need for primate conservation and the importance of primates as a natural heritage in the countries in which they occur.

The IUCN, together with its partners, has long years of experience in assessing conservation status, developing action plans, and implementing conservation action using both local expertise in habitat countries (which is growing rapidly), and expat specialists working in close collaboration. This differs from many other less studied groups of organisms where either the manpower or the expertise, or both, are still in short supply. We know where the highest priority areas are located,

and, with the exception of new species that have been discovered very recently – such as the extraordinary Stryker's snub-nosed monkey (*Rhinopithecus strykeri*) from Myanmar – we have a very good handle on conservation status. With the help of all these plans and publications, the task of amassing both the human and the financial resources needed for implementation is well underway. Although the World Wildlife Fund-US Primate Program no longer exists, many other traditional nongovernmental sources still offer grants for field, captive, and laboratory programs; academic institutions continue to provide funds for primate field studies that have significant conservation impact; government-supported efforts such as the Indo-US Primate Project provide excellent models for international cooperation; and an increasing number of zoos have joined forces to focus on regional primate faunas, generating funds not only for captive breeding programs but also for *in situ* projects. In addition, at least two new significant sources of philanthropic support dedicated to primates have been established in recent years: Primate Conservation Inc. (PCI), and the Margot Marsh Biodiversity Foundation. Several other new endowments also provide considerable annual funding for primate projects, among them the Arcus Foundation and the Mohamed bin Zayed Species Conservation Fund. Together, these organizations and agencies represent the core of funding necessary to move ahead with a global strategy for the most seriously threatened primates, and perhaps to help uncover new sources of support as well.

What we have so far is sufficient funding to deploy these experts into the highest priority places with the greatest extinction risk. Now, however, the time has come to begin ramping up our efforts, specifically in the greater deployment of specialists to carry out all the conservation projects needed. At this point of time, direct action for primates is on the order of \$10 My⁻¹, with more than 90% of that going to the great apes (which constitute only about 2% of the known species and subspecies of primates). To be truly effective, and to ensure that no primate species go extinct in the coming years, we need to increase that by an order of magnitude, to \$100 My⁻¹. Only in this way, we will be able to guarantee that the full diversity of the order Primates is maintained into the new millennium.

The more we learn, the more we see how important primates are – as flagship species for education and awareness efforts for rainforests, as pollinators, and as seed dispersers that may even be instrumental in maintaining high carbon sequestration capacity in the forests of Amazonia, Central Africa, and Southeast Asia. Also, as the need grows to evaluate, verify, and monitor the long-term health of tropical forests, a number of primate species will serve as some of the best indicators of forest health. Although activities under way in many parts of the world make it inevitable that a portion of the world's forests and primates living in them will disappear, our challenge is to try and minimize this loss wherever possible.

Glossary

Acquisition costs Costs of acquiring property rights to a parcel of land. Acquisition of property rights can be total (i.e., the land and title are sold to a conservation agent) or partial. Partial transfers of property rights include short-term land rental, conservation easements, and contracts between conservation agents and landowners who exchange money for land management that enhances conservation value.

Biodiversity Contraction of “biological diversity.” Refers to the variety of life on Earth, including the numbers of, and differences among alleles, genes, individuals, populations, species, communities, and ecosystems. Because this term is very broad, measures of biodiversity typically focus on one aspect of biodiversity at a time (e.g., the number of species).

Conservation planning The science of identifying spatially explicit priorities and actions for the conservation of a region’s biodiversity or natural capital.

Damage costs Costs associated with damages to economic activities arising from conservation programs. For example, damages to crops and livestock from wild animals living in protected areas adjacent to human settlements can result in significant losses in income. In other cases, direct wildlife attacks might physically harm or kill humans, resulting in further economic losses.

Ecosystem services The benefits people obtain (actively or passively) from ecosystems (MEA, 2005).

Efficiency frontier By combining biophysical and/or economic models with optimization methods, one can determine the maximum feasible combinations of values that can be achieved for a landscape. The results can be presented as a frontier, which is defined as the outcomes where it is not possible to improve on any particular objective without decreasing some other objective.

Management costs Costs associated with the management of a conservation program, such as those associated with establishing and maintaining a network of protected areas. Management costs can be fixed and therefore independent of the amount of conservation

activities pursued (e.g., regardless of how much land is protected in an area, an office will need to be opened and a minimal number of staff hired) or variable, such as when a function of the amount and type of conservation intervention.

Opportunity costs Costs of foregone opportunities; that is, a measure of what could have been gained via the next-best use of a resource had it not been put to the current use. In terrestrial protected areas where extractive uses are forbidden, the opportunity cost represents the highest-value extractive use for that land. When purchasing land or conservation easements from private land owners, payments will reflect the value of lost opportunities. With public land or with regulation, direct financial obligations might be divorced from the value of lost opportunities. From a social perspective, it is important to include opportunity costs to track the full set of consequences of conservation planning (Naidoo *et al.*, 2006).

Spatially explicit ecological production function A mathematical expression that translates spatially explicit information on an ecosystem feature or processes to some ecological outcome or condition in the ecosystem. Estimation of production functions isolates the effect of ecosystem services as inputs to the production process. Once an ecological production function is specified, researchers can quantify the impact of landscape change on the level of ecosystem service output.

Transaction costs Costs associated with negotiating an economic exchange. In a terrestrial conservation context, the costs over and above the price of a transfer of property rights to a given parcel of land. These include the costs of searching for properties, negotiating with individual landholders, and obtaining approval for title transfer. Transaction costs can be substantial; for example, carbon sequestration projects involving afforestation or reforestation can be beneficial for conservation, but high transaction costs often limit their viability (Naidoo *et al.*, 2006).

Introduction

Conservation has been called a “crisis discipline” (Pullin, 2002). Indeed, there are several conservation crises – loss and degradation of ecosystems, climate change, to name a few – that impact biodiversity and people’s well-being. Instead of responding haphazardly to one crisis or threat after another, it may be more effective to have a plan that considers not only the present concern (e.g., deforestation) but also develops a

clear vision to avoid future emergencies (e.g., climate change). For these plans to be implemented effectively, it requires acknowledging that conservation does not take place in a sociopolitical vacuum (Sekhar, 2005). A key challenge of modern conservation planning is to anticipate future trends and threats, and develop conservation plans that are as efficient as possible so that they can win the support of stakeholders and provide enough flexibility to adapt to ever-changing conditions (Noss *et al.*, 2002).

Systematic conservation planning is the process of locating, configuring, implementing, and maintaining areas to promote the persistence of biodiversity and other natural values. Moreover, it is an activity whereby social, economic, and political imperatives (i.e., the real world) modify, sometimes drastically, conventional scientific recommendations (see Margules and Pressey, 2000). Historically, the practice of conservation planning was not very systematic and as a result many areas designated for conservation are located on lands, which at the time of establishment were either too remote or unproductive to be economically important (e.g., Pressey *et al.*, 1996). In the case of biodiversity, this means that many species occurring in economically productive landscapes are not protected, although threats (e.g., habitat loss and fragmentation) continue. Indeed, the variety of social, economic, and political goals factoring into conservation planning has led to a diversity of reasons why reserves are established – different proponents see different places differently. Consequently, there has been a perceived competition among stakeholders on how best to target limited conservation resources. Systematic conservation planning has been slowly evolving over the past 25 years to better incorporate these challenges into the planning process (Pressey and Bottrill, 2008).

Most of the early examples of systematic conservation planning set priorities based on biological goals, such as the citing of parks and marine protected areas that maximize biodiversity significance, often measured as the number of endemic or rare and/or threatened and endangered species, and guided by three key concepts: complementarity, irreplaceability, and vulnerability (e.g., Brooks *et al.*, 2006; Spalding *et al.*, 2007; Abell *et al.*, 2008). For instance, Conservation International (CI) has identified 25 biodiversity hotspots that comprise 1.4% of the world's land surface but contain representatives of 44% of known vascular plant species (Myers *et al.*, 2000). Other global conservation plans target areas that maintain ecological and evolutionary processes important for biodiversity persistence (e.g., interspecific interactions, regular and nomadic faunal movements, and disturbance regimes; Cowling *et al.*, 1999; Rouget *et al.*, 2003). For example, World Wildlife Fund – US has divided the terrestrial world into 867 different ecoregions, which are characterized by relatively large areas, each comprising a unique mix of environmental conditions, flora, and fauna. Of these, 233 regions (“the Global 200 (G200)”) represent biodiversity that is globally significant (Olson *et al.*, 2001). These approaches provide a conceptual framework for identifying large-scale conservation area networks but fail to consider the on-the-ground realities that often impede implementation.

As systematic conservation planning evolved, planners of conservation networks also consider the financial and opportunity cost of network conservation and implementation (e.g., Ando *et al.*, 1998). Designating land for biodiversity conservation competes with other societal objectives, such as housing developments, recreation, agricultural or industrial development, and resource extraction. Gaps between analyses of biological data and real-world conservation have become less distinct through time. An initial framework for the process of systematic conservation planning (Margules and Pressey, 2000) showed how this aspect of implementation related to

other tasks. An improved version of this framework made explicit the need to address socioeconomic considerations at the outset (Cowling and Pressey, 2003). Moreover, planning requires consideration of the “enabling process” – how does the foundational science actually get implemented on the ground? Ensuring success requires appropriate institutions and governance structures to exist to enable the effective use of targeted instrumental interventions to address biodiversity loss (Rands *et al.*, 2010). In other words, the revised fundamental goal of systematic conservation planning is to pick a subset of sites for conservation that have high biodiversity or other natural value, are threatened, are cheap, and have broad political and institutional support.

Conservationists have recently begun considering another motivation for conservation: ecosystem services, or the goods and services from ecological systems that benefit people (Daily, 1997). These benefits include the provision of abundant and clean water, climate regulation, food production, and recreation opportunities (MEA, 2005). Changing land use or land management affects not only biodiversity but also the provision and value of a variety of ecosystem services. For example, conversion of forests to croplands results not only in increased food production but also loss of habitat for forest dwelling species, release of carbon to the atmosphere, changes in hydrologic and nutrient cycles, and changes in local weather patterns. Unintended negative consequences for ecosystem services threaten to undermine future human well-being and biodiversity, calling into question whether the current trajectories are sustainable.

Conservation plans that focus on biodiversity alone may direct resources away from ecosystems that harbor few rare or endemic species but which support vital ecosystem services. For instance, a typical *Spartina* tidal marsh has no endemic plants and no more than 30 total plant species, yet this ecosystem provides flood regulation, waste treatment, carbon storage, and fisheries production to human communities (Gedan *et al.*, 2009). How does one best balance these various values when making conservation decisions?

If ecosystem services represent the benefits provided to people by conserved ecosystems, then the costs side of the equation is also important. Communities, governments, and donors are increasingly concerned about the effectiveness of the conservation interventions that they fund (Ferraro and Pattanayak, 2006), and consideration of costs can substantially increase the efficiency of their investments. Incorporating spatial distributions of biophysical benefits and economic costs in conservation planning have shown that limited budgets can achieve substantially larger biological gains than when planning ignores costs (e.g., Naidoo *et al.*, 2006). Although there are potential trade-offs between conservation for biodiversity, for ecosystem services, and considering different economic cost constraints, both in terms of conservation financing and to society at large, a systemic planning framework can help to identify synergies.

The number of potentially competing objectives can complicate conservation planning decisions. In rare cases, the best choice among management alternatives is obvious, such as when one alternative delivers higher levels of all ecosystem services and biodiversity compared with other alternatives (i.e., “win-win” solutions). However, in most cases, comparing

alternative management options will require evaluating trade-offs among various conservation objectives, ecosystem services, and biodiversity conservation. The authors, herein, describe recent research that is advancing these frontiers. They cover: Why it is important to consider ecosystem services and costs, along with biodiversity, in the planning process; examples of how ecosystem services can be estimated or modeled in a spatially explicit manner; examples of how plans differ when ecosystem services and costs are formally considered; how costs can fit into a dynamic framework for conservation planning; and end by discussing limitations and future directions for research that integrates biodiversity, ecosystem services, and cost effectiveness in conservation planning.

Broadening Conservation Planning with Ecosystem Services

Efforts to jointly conserve biodiversity and ecosystem services will likely be inefficient unless objectives for both are explicitly considered. Maps of species occurrences and ecosystem ranges provide important data; however, it is also important to consider the distribution and associated pressures of human populations. For example, as of 1995, more than 1 billion people lived within CI's 25 biodiversity hotspots at an annual rate of population growth 40% higher than the global average (Cincotta *et al.*, 2000). The reality of expanding human populations within biodiversity hotspots has led to recent calls from conservationists to include among their targets ecosystem services as well as biodiversity (Balvanera *et al.*, 2001).

The Millennium Ecosystem Assessment (MEA, 2005) documented the importance of ecosystem services to human well-being and showed that continued supply of these services is threatened by unsustainable human activity. Several conservationists have rallied around the idea that the public is more likely to support land protection if the land harbors not only a long list of species but also provides recreational opportunities, flood protection, clean water, and climate regulation – ecosystem services that improve people's well-being (e.g., The Nature Conservancy, 2011). However, more work is needed to better understand the scope for alignment between conservation of biodiversity and areas most important for delivering ecosystem services. Systemic conservation planning provides a good framework for transparent reporting of the trade-offs across targets – where are the potential areas where biodiversity and ecosystem services align and where they do not?

Researchers are newly able to quantify and map ecosystem services in ways analogous to the biodiversity maps used by conservation planners (e.g., Kareiva *et al.*, 2011). For instance, recent work developing and integrating ecological production functions to quantify ecosystem services into an economic framework has made several important advances. First, models have become spatially explicit. In a series of articles, Sanchirico and Wilen (1999, 2001, 2005) developed a bioeconomic model that considered distinct habitat patches and dispersal of a harvested or game species. Others have developed spatially explicit models of ecosystem services

as a function of land use and land cover (e.g., Lewis and Plantinga, 2007; Nelson *et al.*, 2008, 2009; Polasky *et al.*, 2008).

Second, models have expanded beyond a single-service focus to consider provision of the bundle of ecosystem services jointly produced by the ecosystem (e.g., Antle and Stoorvogel, 2006; Boody *et al.*, 2005; Coiner *et al.*, 2001; Naidoo and Ricketts, 2006; and Nelson *et al.*, 2008, 2009). Such work allows an analysis of the trade-offs in provision among services, which provides information on the optimal spatial arrangement of land use and land management to meet multiple conservation objectives (e.g., Nelson *et al.*, 2008, 2009; and Polasky *et al.*, 2008).

Consideration of Biodiversity and Ecosystem Service Targets

Important insights on the spatial concordance of biodiversity and the provision of ecosystem services have been revealed from recent studies. At the global scale, studies have shown that regions identified as priorities for traditional conservation reasons, such as their inclusion of endemic species, high biodiversity, or threatened habitats, are not necessarily those that provide the greatest provision of ecosystem services (e.g., Turner *et al.*, 2007; Naidoo *et al.*, 2008; and Larsen *et al.*, 2011).

Naidoo *et al.* (2008) used available global datasets on species distributions within ecoregions and four ecosystem services (carbon storage and sequestration, livestock production, and water yield) to illustrate potential synergies and trade-offs between these targets. They found little spatial concordance among individual services and species, which is in accordance with findings for global range-restricted species (Larsen *et al.*, 2011) and, at a more regional scale (Anderson *et al.*, 2009). When they asked whether existing priority areas (biodiversity hotspots, high-biodiversity wilderness areas (HBWAs), and G200) effectively conserve ecosystem services, they found that service provision in the three schemes varied depending on whether these services were locally versus globally consumed (Figure 1). For example, carbon services, which are globally dispersed, were highest in low human-density HBWAs; conversely, locally dispersed services, water yield, and livestock production were highest in areas near densely populated areas, such as biodiversity hotspots. Similarly, Larsen *et al.* (2011) found that the level of concordance with range-restricted species could vary across different services and suggest that particular regions and service combinations can be used to reveal synergies and tradeoffs.

Although measures of biodiversity and ecosystem services do not tend to correlate well, it does not mean that this approach to conservation planning is futile. Indeed, Naidoo *et al.* (2008) not only identified several global priority areas as potential locations where both biodiversity importance and ecosystem services importance were relatively high (those ecoregions in the upper right hand corner of Figure 2) but also, and just as informative, the areas where there are trade-offs (Naidoo *et al.*, 2008).

Global analysis relying on such coarse data may not be relevant to on-the-ground conservation efforts. However, the same poor correlation between biodiversity and ecosystem

Figure 1 Mean amount of ecosystem services per unit area provided by three global conservation priority schemes. (a) Carbon sequestration. (b) Carbon storage. (c) Grassland production of livestock. (d) Water provision. Horizontal lines represent the global mean for each service. Three global biodiversity priority schemes are biodiversity hotspots, G200, and HBWA. services described above (Naidoo *et al.*, 2008) also appears at finer scales. For example, in California's Central Coast ecoregion, biodiversity was mapped with a variety of ecosystem services: pollination, carbon storage, recreation, water storage, flood control, and forage production (Chan *et al.*, 2007). By applying the standard site-selection algorithms in MARXAN (Ball and Possingham, 2000), Chan *et al.* (2007) identified a network of protected areas capturing both biodiversity targets and ecosystem services. This network required 10–20% increase in the area of protected land beyond what was needed for biodiversity alone. Thus, just as seen at the global scale, individual sites can be identified that are relatively high in both biodiversity and ecosystem service value, regardless of a poor overall correlation between the two. Other regional and local studies across geographies have shown similar findings (e.g., Anderson *et al.*, 2009; Egoh *et al.*, 2009; Nelson *et al.*, 2008; and Bai *et al.*, 2011).

Indeed, in some cases a conservation policy directed toward only one target can actually reduce the ability to attain the other goal. For instance, in the Willamette Basin, Nelson *et al.* (2008) showed that conservation payment policies aimed at increasing the provision of carbon sequestration do not necessarily increase species conservation and that highly targeted policies do not necessarily perform as well as other general conservation payment policies. For example, at-risk vertebrate species were maximized when landowners accepted

Figure 2 Relationship between ecosystem service importance and conservation importance. Each axis is the rank order (low to high) of 574 terrestrial ecoregions in terms of per-area carbon storage (y-axis) or area-corrected number of endemic species (x-axis; calculated as Number of endemic species per area^{0.25}). Lines indicate median values for each variable. Diamond in quadrant 4 represents the California Central Coast ecoregion. Reproduced from Naidoo R, Balmford A, Costanza R, *et al.* (2008) Global mapping of ecosystem services and conservation priorities. *Proceedings of the National Academy of Sciences of the United States of America* 105: 9495, with permission from PNAS.

payments to restore rare natural habitats, including oak savanna, prairie, and emergent marsh. Carbon sequestration, however, was maximized when landowners accepted payments to restore or conserve forests, including old growth, mixed, and riparian forest. Indeed, maximizing forest cover did benefit some species (e.g., the spotted owl); however, it provided little benefit for most of the 37 rare species analyzed. Thus, if conservation programs that pay for ecosystem services are not designed carefully, they may yield minimal gains in services of interest and may well result in harm to other services or biodiversity conservation.

Importance of Considering Cost-Effectiveness and Cost-Benefits

Unfortunately, conservation plans cannot be implemented for free. By ignoring the cost side of conservation planning, we are missing the opportunity to more efficiently implement conservation objectives given the reality of limited global conservation funds (Naidoo *et al.*, 2006). Just as biodiversity is not evenly distributed over landscapes (e.g., Orme *et al.*, 2005), the same is true for economic costs and this spatial variability should be considered in conservation planning (e.g., Ando *et al.*, 1998; Polasky *et al.*, 2008). Ignoring the spatial variation in costs has led to conservation plans that are at best far from optimal and at worst economically indefensible.

Conservation costs can be thought of in several major categories: acquisition costs, management costs, transaction costs, damage costs, and opportunity costs. A high cost of one type does not necessarily indicate a high cost of other types. For example, a forested parcel adjacent to a road may have low management costs, due to its accessibility, but high acquisition costs because of its proximity to urban development. Such parcels, because of their proximity to urban areas, are typically prime targets for land-use conversion, in this case forest to development, because the opportunity for keeping the land forested are much too high, as represented by the high value of using the land for development instead of forestry. From a social perspective, it is important to include opportunity costs, or the lost opportunities, to account for the full cost of conservation planning.

Most of the systematic conservation planning literature has focused on efficient representation of biodiversity in reserves (see Margules and Sarkar, 2006). For example, a retrospective analysis of a \$2.8 billion land investment for conservation lands and easements between 1990 and 2006 in California, USA, showed that four times as many species and five times as much land could have been conserved if a return-on-investment algorithm had been used (Underwood *et al.*, 2008). In terms of how conservation benefit per dollar spent could affect global funding priorities, priority funding for CI's terrestrial biodiversity hotspots based solely on different biodiversity values (i.e., single taxonomic groups and endemics) did not overlap well, whereas factoring in economic costs of working in different regions revealed plans with much higher concordance (Bode *et al.*, 2008). However, it is worth noting that, typically, conservation funds cannot be spent just anywhere on anything.

Another study of global priority areas sought to maximize mammalian species per area and identified 11% of the Earth's surface for conservation attention (Carwardine *et al.*, 2008). However, these areas directly overlapped high value areas of agricultural production and dense human settlements – a classic example of conflict between people and conservation goals. Yet, a reanalysis of the distribution of the world's mammals, with a focus this time on cost-effectiveness, revealed a different picture. When planning algorithms sought to minimize conflicts between protected areas and crop production, an ecosystem service, the area of conflict was halved, whereas the total area needed to protect the world's mammals increased by less than 2% (Carwardine *et al.*, 2008).

Although conservation-planning efforts targeting protected areas are important for conserving many rare species, this approach sometimes ignores the potential conservation benefits of less “pristine” lands (e.g., agricultural or developed lands). There are relatively few examples of systematic conservation planning that explicitly consider the entire range of land cover and land management practices in a region, yet many species can coexist with some level of human activity (Pennington and Blair, 2011). The broader conservation question, beyond the question on where are the best places to locate reserves, is whether conservation objectives can be met on a landscape that includes both working lands and protected lands. Land-use decisions on working lands are based primarily on economic criteria, whether it is the local people using land to make a living or the corporations using land to maximize profits. Although land-use decisions based solely on economic returns are often detrimental to biodiversity, securing some economic return from land need not be mutually exclusive with biodiversity conservation. By thinking carefully about the pattern, extent, and intensity of human activities across the landscape, it may be possible to achieve important biodiversity conservation objectives while also generating reasonable economic returns.

For example, Polasky *et al.* (2008) developed a spatially explicit landscape-level model to analyze the biological and economic consequences of alternative land-use patterns for the Willamette Basin in Oregon, USA. In that study, researchers combined biological and economic model results, total number of species, and value of marketed commodities (including agriculture and timber output, both are provisioning services but for this study are not explicitly considered as so, and urban development), respectively, to search for efficient basin-wide land-use patterns using optimization methods from operations research. An efficient land-use pattern is one that generates the maximum number of species conserved for a given economic return (and vice versa). By maximizing the total number of species over the entire range of possible economic returns, one can trace out an efficiency frontier for the landscape (Figure 3). The efficiency frontier illustrates what can be achieved in terms of biological and economic objectives by carefully arranging the spatial allocation of activities across the landscape. In this case, Polasky *et al.* (2008) found land-use patterns that sustain an expected 249 species, 97% of the total number of species found for the landscape, and \$25.4 billion in economic returns, 92% of the maximum economic value (point D, Figure 3). The efficiency frontier also demonstrates the degree of inefficiency of

Figure 3 Land-use patterns associated with specific points along the efficiency frontier and the current landscape. Each land-use pattern shown outside of the efficiency frontier corresponds to a lettered point on the frontier. The current land-use pattern is also shown (I). Compared with the current landscape, points on the efficiency frontier have less agriculture and more residential use. There is a shift from predominantly managed forest toward conservation land as the biological objective, number of species, is emphasized more relative to the economic objective, returns from agriculture, forestry, and development. Abbreviation: UGB, urban growth boundary. Reproduced from Polasky S, Nelson E, Camm J, *et al.* (2008) Where to put things? Spatial land management to sustain biodiversity and economic returns. *Biological Conservation* 141: 1505–1524, with permission from Elsevier.

other land-use patterns not on the frontier. For example, the business-as-usual land-use pattern for the basin only sustains 238.6 species and generates \$17.1 billion in economic returns (point I, Figure 3). These results indicate how proper attention to spatial management can limit trade-offs between biodiversity conservation and economic returns.

Incorporating Biodiversity, Ecosystem Services, and Economic Considerations

In its ideal form, a conservation planning effort should consider biodiversity as well as multiple ecosystem services, and estimate monetary values of both benefits and costs to ease comparisons and decisions. Including biodiversity and multiple benefits is important because it allows for the explicit evaluation of potential tradeoffs and broadens the planning conversation by considering conservation goals for biodiversity and for human well-being. Monetary valuation is useful because it can help to assess tradeoffs by making the costs of environmentally damaging activities more apparent. Estimating the monetary value of ecosystem services has been a focus of much recent research. For provisioning services where established markets exist, such as agriculture and forestry, determining economic value is relatively straightforward (e.g., Polasky *et al.*, 2008; Nelson *et al.*, 2009). For those goods

and services where no current market exists, such as water filtration, economic valuation can be much more difficult (Freeman, 2003).

The studies described so far in this article strongly incorporate some of these components. But only a very few studies explicitly combine them all into full assessments. For example, although there have been many studies that quantify the opportunity cost of providing a single ecosystem service (e.g., Kindermann *et al.*, 2008 for carbon sequestration; Swallow *et al.*, 2009 for sediment delivery) and similarly for biodiversity conservation (e.g., Naidoo and Ricketts, 2006; Polasky *et al.*, 2008), there have been relatively few studies on the joint provision and value of multiple outcomes (multiple ecosystem services, biodiversity, and returns to landowners) from ecosystems. Several studies have characterized the spatial overlap among ecosystem service provision and biodiversity conservation (e.g., Chan *et al.*, 2006; Egoh *et al.*, 2008; Naidoo *et al.*, 2008; and Nelson *et al.*, 2009), but these studies have not analyzed how alternative land-use or land-management decisions affect the provision and value of ecosystem services or biodiversity conservation (Polasky *et al.*, 2011). Integrating biodiversity, ecosystem services, and economic costs into systematic conservation planning is a new area of research that seeks to broaden the cost considerations beyond those of conservation donors to society and policy makers at large.

In this final section, some of the recent studies that have moved conservation toward doing the “full monty” are described.

Naidoo and Ricketts (2006) served as a landmark example of incorporating multiple ecosystem service values into the

traditional context of conservation site selection. They mapped, the monetary value of five ecosystem services (sustainable bushmeat harvest, sustainable timber harvest, bioprospecting, existence value, and carbon storage) in the Mbaracayu Forest

Figure 4 Economic values (net present values in US\$ per hectare) in the Mbaracayu Forest Biosphere Reserve. (a) Sum of all 5 services. (b) Sustainable bushmeat harvest. Biosphere Reserve in Paraguay (see [Figure 4](#)). By also estimating opportunity costs, they were able to show areas where conservation values would more than cover the costs of conservation and other areas where the converse is true. [Naidoo and Ricketts \(2006\)](#) used these maps to evaluate three alternative locations for a proposed corridor linking two protected areas, and they found that one corridor provides much higher benefits relative to costs than the other two. This is an example of how these approaches of mapping and valuing ecosystem services can help direct conservation efforts.

Moving toward the “full monty” approach to systematic conservation planning, [Nelson *et al.* \(2009\)](#) compared biodiversity conservation, multiple ecosystem services, and economic outcomes under three alternative land-use trajectories for the period 1990–2050 for the Willamette Basin ([Figure 5](#)). They found that all biodiversity and ecosystem service measures were highest under a conservation scenario, but economic returns to landowners were higher under more development oriented scenarios. However, including payments for carbon sequestration alleviated this trade-off ([Figure 6](#)).

For the state of Minnesota, USA, [Polasky *et al.* \(2011\)](#) modeled biodiversity conservation, the provision of multiple ecosystem services, including carbon sequestration, water quality, agricultural production, and urban development. They compared historical land-use change during 1992–2001 in addition to alternative scenarios of future land-use change: no urban expansion; no agriculture expansion; agricultural expansion; forest expansion; and a conservation scenario where riparian areas and marginal agricultural lands are restored to presettlement vegetation. Not surprisingly, they did not find a single land-use scenario that maximized the levels of all ecosystem services as well as habitat for biodiversity. A conservation scenario was best for the reduction of phosphorus exported into the Mississippi River, but a no agricultural expansion scenario was best for carbon sequestration.

The best scenario for habitat provision depends on the group of species being considered.

Like [Nelson *et al.* \(2009\)](#), they found a lack of concordance in the ranking of scenarios between net social benefits (non-market and market values, including carbon sequestration, water quality, agriculture and forestry production, and urban development) and the market value of returns to landowners (agriculture and forestry production, and urban development), which suggests that there is a large role for public policy in land-use decisions. For example, the agriculture expansion scenario, where all highly productive lands were put into agriculture, delivers the lowest total economic value across scenarios despite the fact that it delivers the highest financial returns to landowners in terms of crop sales.

Another example of simultaneously assessing multiple ecosystem services uses a bioeconomic model of a coral reef–mangrove–seagrass ecosystem to investigate the contribution of mangroves toward providing storm protection and as a nursery for coral reef fish, and also incorporate market values of converting mangroves into aquaculture ([Sanchirico and Springborn, 2011](#)). The authors’ results show that considering multiple services can mitigate the level of payments for ecosystem services needed to ensure the delivery of other services, in this example fishing, thus, highlighting the importance of including multiple services in order to minimize financial payments. By including multiple ecosystem services, each stakeholder group that benefits from an ecosystem process with multiple services is likely to have lower costs relative to a situation where fewer services are considered, everything else being equal. Even in the case of degraded coral reef–mangrove–seagrass ecosystems, services thereof exceeded the market returns from aquaculture, highlighting the importance of expanding conservation considerations to include marginal and degraded systems as well as the pristine.

Figure 6 Tradeoffs between market values of commodity production and biodiversity conservation on the landscape between 1990 and 2050, excluding (circles) and including (triangles) the market value of carbon sequestration. The x-axis measures the total discounted value of commodities, whereas the y-axis measures the biodiversity score. Reproduced from Nelson E, Mendoza G, Regetz J, *et al.* (2009) Modeling multiple ecosystem services, biodiversity conservation, commodity production, and tradeoffs at landscape scales. *Frontiers in Ecology and the Environment* 7: 4–11, with permission from ESA.

Conclusions

Even in the well-developed field of systematic conservation planning, spatially explicit models of ecosystem services can broaden the information available to planners and improve decision making. As shown above, mapping and quantifying ecosystem services and biodiversity conservation in a spatially explicit manner, and analyzing trade-offs between them, can help to make natural resource decisions more effective, efficient, and defensible. Integrated landscape-level analysis that tracks change across a number of dimensions of ecosystem services and biodiversity conservation is still a relatively young discipline. Application of such models, however, can generate information for decision makers showing the consequences of choices for a range of important ecosystem services and biodiversity conservation objectives (Groves, 2003). In principle, putting this information in the hands of decision makers should lead to improved landscape planning and management (Daily *et al.*, 2009).

Remaining Challenges

Many challenges remain before reaching this Promised Land. These include improving and validating the component models for ecosystem services (e.g., De Groot *et al.*, 2010; Balmford *et al.*, 2011). Researchers applying these models should also conduct sensitivity analyses to determine whether errors in the biodiversity, ecosystem services, or economic data could affect conservation outcomes. For example, Bode *et al.* (2008) found that conservation outcomes were most sensitive to uncertainty in the land cost data, followed by the habitat loss rates, and finally the biodiversity data. Indeed, these errors are likely largest in the cost or economic data, especially for nonmarket valuation. Indeed, Bode *et al.* (2008) found that these errors could result in inefficient funding strategies causing 20 times as many extinctions as errors of the same proportional size in the biodiversity data, and 6 times as many extinctions as errors of the same proportional size in the habitat loss rates.

Translating from biophysical units to monetary value units is problematic for biodiversity targets and some types of ecosystem services (e.g., Freeman, 2003). For example, trying to estimate the values of cultural and spiritual values is difficult and controversial. For some ecosystem services, estimating monetary values using market prices or applying nonmarket valuation techniques may be relatively straightforward (e.g., provisioning services (Naidoo and Ricketts, 2006; Polasky *et al.*, 2008, 2011; Nelson *et al.*, 2008, 2009) and crop pollination, which is an input to a priced commodity (Ricketts *et al.*, 2004)).

Even with our growing knowledge of biophysical systems, understanding the provision of ecosystem services also requires detailed understanding of what is of value to people. It is important to recognize that estimates of value used to identify spatial priorities, to evaluate trade-offs, and for most other results reviewed here, depend on the choice of ecosystem services to include. Moreover, evaluating multiple services can elicit unexpected outcomes and trade-offs (e.g., Polasky *et al.*, 2011).

Another important set of issues relates to land-use change and dynamics. Most conservation planning research has been static. In the examples presented above, the authors analyzed “steady-state” consequences of a landscape in terms of biophysical and socioeconomic objectives. However, the on-the-ground reality is that there is an existing landscape and changes will occur over time. For example, if the current land use is soybeans but the desired land use is a managed forest, it will take several years for trees to grow to maturity for harvest, thus resulting in a significant delay between land-use change and the actual start of forestry activities or other natural capital benefits. Also, through this period of forest growth there could be unforeseen events, such as fire or pest outbreaks or long-term impacts caused by climate change that could lead to unexpected transitions. In turn, species or ecological processes would take time to adjust. Furthermore, human population changes and shifts in markets or societal values will result in changes in the benefit of different land uses over time. All of these will affect the relative costs and benefits of investing in conservation and mean that at any given time decisions on what and where to conserve are changing.

Stochastic Dynamic Programming (SDP) is a framework for modeling optimization problems that involve uncertainty (Clark and Mangel, 2000). In conservation planning this approach has been used to find the optimal allocation of investment at each time step given the current state of the system and possible events in the future. Currently, applying SDP to problems over large areas is computationally intractable. However, there have been a few articles that analyze an optimal sequence of conservation decisions using SDP, such as schedule investments over time (e.g., Costello and Polasky (2004); Wilson *et al.*, 2006). For example, Wilson *et al.* (2006) applied SDP using information on how investment returns change through time and found that simple ranking schemes yield fewer benefits per dollar than a return-on-investment approach, suggesting that conservation actions are not independent of each other. The protection of a particular parcel of land because it is biologically valuable and also threatened by conversion may simply displace the threat to nearby areas.

Costello and Polasky (2004) showed that conservation budgets available upfront yield significantly greater biodiversity protection and highlight the importance of the timing of protected area selection. In addition, the purchase of properties for a new protected area may drive land prices up due to increased demand for land for other purposes. This can have perverse effects on local communities and also make it more expensive to establish additional protected areas. This shows how investment decisions by conservation organizations themselves change the state of play and resulting land market prices. There are approaches for predicting and incorporating negative feedbacks in dynamic conservation planning situations. Using the knowledge of the dynamics of the local market, Armsworth *et al.* (2006) showed that whenever a parcel of land is purchased, the relative price of other parcels of land is altered. Similarly, the likelihood of success can be updated in a similar manner. Future work in conservation planning should consider these dynamics and transitions.

Finally, our understanding of these techniques to model ecosystem services and trade-offs far exceeds our ability to

apply them effectively to pragmatic conservation problems (Knight *et al.*, 2006). Improving our understanding of meaningful ways to embed this approach into larger policy decisions is paramount. Importantly, what is attractive about this approach in terms of planning decisions is that it does not require agreement on (1) the motivations underlying the tradeoffs that individual people are willing to make (i.e., the reasons that people want to protect ecosystems) or (2) what considerations beyond an assessment of trade-offs should enter into public policy decisions (Polasky and Segerson, 2009). By recasting the conservation planning discussion to focus on the relevance and assessment of trade-offs, it increases the likelihood that all participants will be able to find greater common ground for collaboration, even if they hold very disparate views on other issues. In turn, this should allow greater progress toward designing and implementing policies or plans designed to protect not only the biodiversity but also the ecosystems and the services they provide.

Reforestation

David Lamb, University of Queensland, Brisbane, Australia

Glossary

Degradation A temporary or permanent loss of forest structure, productivity, and native species diversity. A degraded site might still contain trees (i.e., a degraded site is not necessarily deforested) but it has lost at least some of its former ecological integrity and has a lowered capacity to supply goods or services.

Ecological restoration To re-establish the presumed structure, productivity, and species diversity of the forest originally present at a site. The ecological processes and functions of the restored forest will closely match those of the original forest.

Plantation monoculture A plantation forest involving a single species. The original biodiversity at a site is not

recovered although the protective function and many of the original ecological services may be re-established.

Reforestation The re-establishment of trees and understory plants at a site previously occupied by forest cover. This can occur by natural means or by some form of human intervention including planting seedlings or sowing seeds.

Rehabilitation To re-establish the productivity and some, but not necessarily all, of the plant and animal species thought to be originally present at a site. For ecological or economic reasons, the new forest might also include species not originally present at the site. The protective function and many of the ecological services of the original forest may be re-established.

Introduction

Biodiversity and productivity are lost when natural forest ecosystems are fragmented or cleared. Reforestation is used to reverse this process but this can take a variety of forms. In some cases natural regeneration may occur and be sufficient to restore forest cover but, in other cases, direct seeding or planting seedlings will be necessary if reforestation is to occur within a reasonable time. Reforestation is often used to simply restore productivity but significant proportions of plant and animal biodiversity can also be reestablished if appropriate silvicultural techniques are used. The extent to which biodiversity is restored depends on (1) the type of reforestation, (2) the area covered, and (3) its location within the landscape. True ecosystem restoration is very difficult and more modest goals are often all that is possible, particularly over large areas. Successful reforestation usually requires solving social and economic problems as well as just ecological problems. These socioeconomic issues are often the most difficult to resolve because the benefits of reforestation may take some years to develop whereas the costs to landholders are immediate.

Need for Reforestation

Large areas of the world's forested lands have been cleared to enable agricultural development. Estimates by the Food and Agricultural Organisation of the United Nations (FAO) (2010) suggest the annual net rate of loss in forest cover was 8.3 million hectare between 1990 and 2000 and 5.2 million hectare between 2000 and 2010. Even if the rate of the world's population growth is reduced and human populations are stabilized, it is possible that much more of the world's remaining natural ecosystems will be cleared. Many of these cleared lands have been used for food or fiber production but

large areas have simply been degraded through misuse and then abandoned. In the face of this process of biological simplification, much effort has gone into developing a comprehensive, representative, and adequate series of nature reserves to protect the remaining biodiversity. There are doubts about the effectiveness of this network because most reserve areas are isolated and often cover only a small proportion of the landscape. More biodiversity might be protected if some of the under-used degraded lands could be reforested and different components of the reserve network could be linked together.

Methods of Overcoming Degradation

Degradation is a subjective term. A newly cleared area of forest might be regarded as prime agricultural land by a farmer but as degraded wildlife habitat by a bird enthusiast. To some extent, degradation is in the eye of the beholder. However, many would agree that once-forested land that has lost both its structure and diversity and is not used in any productive way is now, in some sense, degraded. This view would be re-enforced if economic productivity had also been reduced. The two main ecological components of degradation are shown in **Figure 1**. One component is the proportion of the original biodiversity still present and the other is the proportion of the original structure or productivity remaining. The original undisturbed ecosystem is at point A and point B which represents the same site in a degraded state. The degraded area now has less biodiversity and is at a lower level of productivity or structure. The degraded site might degrade even further, perhaps because of recurrent fires (point C) or, if not disturbed further, might gradually recover, unaided, back to point A. The circumstances under which this recovery could occur are described further below.

Figure 1 Various methods of reforestation after degradation. Degradation has moved the system from its original state at point A to a degraded state at point B. Over time, the site can degrade further to C or recover naturally back to A. Reforestation via plantation monocultures can lead the system to D1 or D2, depending on the productivity achieved. Rehabilitation may recover most of the structure and productivity but only part of the former biodiversity (E). Over time, some of the original species may recolonize the forests at D and E from intact forest, causing them to drift back toward point A. (After Bradshaw, 1995. Reprinted from Cairns J (ed.) (1995) *Rehabilitating Damaged Ecosystems*. Lewis Publishers.), with permission from CRC Press.

The process of recovery can be accelerated by reforestation but there are several ways in which this might be done. Each leads to a different outcome. *Restoration* (or, more properly *Ecological Restoration*) describes the process in which the aim of reforestation is to restore the ecosystem back to its former condition (point A) containing the original complement of plant and animal species. At this point the ecosystem will have regained its original structure and productivity and the ecological processes that sustained the system will have been reestablished. Reforestation using *plantation monocultures*, however, attempts to restore structure and productivity but not the original biodiversity (point D). Such reforestation is commonly undertaken for commercial reasons and often uses exotic tree species. The structure and productivity may be partially regained (point D1) or even exceed that of the original ecosystem because of the use of fertilizers or other management inputs (point D2).

Between these two approaches lies a midway position that might best be described as *rehabilitation*. This may recover the original structure and productivity but may not recover all of the original biodiversity (point E). The new ecosystem may contain a mix of native and exotic species. Over time, the new systems at D and E may gradually drift toward point A if some of the original species are able to recolonize from intact forest nearby or they may remain in a partially restored state if no such recolonization takes place.

These three forms of reforestation are a necessary simplification of the variety of methods of reforestation that might take place on degraded lands. They differ in the degree to which biodiversity is recovered but they also share certain common attributes. These include the fact that a new stable and productive land use is achieved and that at least

some of the ecological services and protective functions of the original forest have been recovered.

Can Restoration Ever be Achieved?

Some have questioned if reforestation can ever achieve complete ecological restoration and recover all the biodiversity once present at a degraded site (Lamb, 2011). There are several problems. One is that the term restoration implies that the original species complement at a site is known and thus that there is a clear target. The second is the assumption that this community would have persisted over time when, in fact, the target may have drifted because of the changes in climatic or other environmental conditions. The third problem is that the process of degradation may have caused certain of the original species to go extinct whereas some exotic species became naturalized. These difficulties mean that restoration is sometimes an uncertain target that might be difficult to achieve in practice. For these and other reasons, the [Society for Ecological Restoration](#) defines ecological restoration as

the process of assisting the recovery and management of ecological integrity. Ecological integrity includes a critical range of variability in biodiversity, ecological processes and structures, regional and historical context, and sustainable cultural practices.

Ecological restoration may also be difficult for other reasons. In some severely degraded sites the numbers of species to be restored may be too high or the magnitude of the environmental changes (e.g., to soil fertility or salinity) may be so immense that restoration is too difficult to achieve even if the technical means were available. In such cases the financial costs of attempting to fully restore the original system might simply be too high. In some situations social constraints may also apply. For example, some landowners or managers may be unwilling to agree with reforestation of degraded sites because their opportunity costs are too high and the restoration of biodiversity conservation is not a goal they share. However, such persons may be quite willing to undertake other forms of reforestation that generate economic benefits and, coincidentally, some conservation benefits.

Methods of Reforestation

Reforestation can take place in a variety of ways. In some situations degraded forest ecosystems can regenerate without human intervention. A well-known example is the reforestation that has occurred over the past 100 years in much of the north-eastern US following the abandoning of some of the land previously cleared for agriculture. The former farm sites are now occupied by deciduous woodlands with a structure and diversity probably similar to that which was originally present. This same natural recovery process can be found in many other temperate and tropical forests (Stanturf and Madsen, 2005; Lamb, 2011). The rate at which such successions take place varies widely but most are usually slow. Natural recovery after degradation is not an inevitable process and it only takes place under certain conditions. In all cases

the disturbing agents that were the causes of degradation must have been removed and the original topsoils must have remained more or less intact. Further, remnant communities of the original forest species must have persisted nearby in the landscape to act as a source of propagules and colonists for the new succession.

A particular problem with such slow recovery processes is that it prolongs the risk that sites might get damaged again by disturbing agents such as fire or grazing. If this occurs the site can be degraded once more (taking it back once more to point B or C on [Figure 1](#)). Another problem with natural recovery is that it might not be recognized as being underway. In these circumstances the risk is that the site may be seen as abandoned wasteland and open to use by newcomers. For these reasons, more active reforestation programs may sometimes be needed to accelerate the process and overcome these risks. These direct reforestation programs can take a variety of forms but all require that the causes of degradation (fire, grazing, invasive species, firewood collection, etc.) be removed and that sites be actively protected. The subsequent reforestation process can then be carried out by direct seeding or by planting seedlings.

Direct Seeding

The advantages of direct seeding are that a costly nursery stage is avoided and seeds can be broadcasted in the field comparatively cheaply. Seeds can be sown by hand or from a vehicle or can be distributed from the air and large areas can be covered relatively quickly ([Figure 2](#)). The disadvantage of direct seeding is that only a small proportion of the seed distributed is likely to reach the seedling stage as many seeds are removed by animals or insects, fail to germinate under field conditions or are out-competed by weeds. This means that direct seeding usually requires large volumes of seeds to achieve a desired tree density and it may be impossible to acquire such volumes for many less-common species. Direct seeding has often been used at mine sites where topsoil has been respread after mining has ceased and where competing weeds have not yet re-established. Direct seeding is also possible in areas where competing weeds can be removed by plowing or the use of weedkillers. In such circumstances a cocktail of species might be reintroduced as seeds although the diversity of species in such a mix can be limited by the availability of seeds of less-common species and these might have to be re-established at the site as seedlings.

Planting Seedlings

Planting of seedlings raised from seed (or cuttings) in a nursery is a more expensive operation but it may be necessary for species with very small seeds or particular germination or mycorrhizal requirements. It also necessitates other management inputs such as site preparation (ripping or plowing), weed control, or fertilizing which improve survival and foster more rapid growth of the planted seedlings. In plantation monocultures being established for commercial reasons, it is common to plant trees in regularly spaced rows. This also permits the use of planting machines pulled behind tractors

Figure 2 Forest establishment after direct sowing of seeds from the air at a bauxite mine in northern Australia. Some supplementary plantings of certain species can also be done where seeds are difficult to collect or where germination and establishment of these species in the field is poor, with permission from P. Erskine.

which can lead to very rapid planting rates. In a restoration operation a more irregular planting design might be preferred because it leads to a more random distribution of species.

The Choice of Species

A key issue in all reforestation is the identity of the species to use. If the goal of reforestation is commercial timber production, then a fast-growing, exotic species might be chosen. Such species usually have readily available seed, well-established nursery and planting methods, and defined silvicultural prescriptions to govern their management. If, however, ecological restoration of a former ecosystem is the goal, then only native species will be used. But this can be difficult to achieve. In many cases it may not be possible to acquire the seed of all of the original species or to raise large numbers of seedlings of those needed. In many cases environmental or socio-economic constraints may mean that ecological restoration is not possible and that some form of rehabilitation must be adopted. In that case it may be useful to use species that provide both economic and conservation benefits. These may include native and exotic species. Some of the types of species that might be used are shown in [Table 1](#). These include economically useful species, those able to tolerate or modify the new site conditions, those attractive to particular wildlife or those not able to reach the site through normal dispersal mechanisms.

Table 1 Plant species that might be chosen for reforestation programs

<i>Type of species</i>	<i>Reason</i>
Native species	To restore the original communities once present at the site; where possibly the seed of these species should be collected from local sources
Exotic species	Since only exotics can tolerate the conditions now present at the degraded site or because they are fast growing and provide a commercial return
Commercially useful species	For example, providing timber, fruit, oils, and nuts; a financial return is needed to justify funding of reforestation
Traditionally or culturally useful species	For example, those providing fuel, food, or medicines used by local communities
Tolerant species	Able to tolerate the adverse conditions likely to be found at degraded sites such as low soil fertility, exposed windy conditions, soil salinity, or occasional fires; in some cases, only exotic species may have the required attributes
Species with fleshy fruit	To attract seed-dispersing frugivores to the site
Poorly dispersed species	Species with large fruit or those with high specialized animal dispersers unable to tolerate the habitats now present at the degraded site
Nitrogen-fixing species	To improve soil nitrogen levels
Fast-growing species	To rapidly occupy the site, shade out weeds, and improve microclimatic conditions
Understory species	To provide the structural complexity and habitat conditions required by some wildlife species
Multipurpose species	Trees that fulfill more than one requirement such as providing timber and food
Special species	Species required for some special purpose; e.g., rare or endangered trees requiring enlarged populations, "keystone" species producing food required by wildlife at certain times of the year, etc.

Forestry is a long-term business and management objectives for a particular forest can change over time. In some areas plantations established for timber production have acquired a greater value as recreation or conservation reserves. In these circumstances it may be useful to manipulate the composition of the forest to favor these new management objectives (*see* Case Study 1).

Planting Densities and Species Richness

The choice of planting density and the number of species planted will be determined by the objectives of reforestation and the resources available.

Planting Densities

Commercial tree growing in well-watered temperate or tropical locations usually requires moderately close initial spacings (perhaps 1100 trees per hectare) to exclude weeds and ensure rapid site occupancy. Close spacings also reduce side branching and promote rapid height growth. Where ecological restoration is the objective, close spacings might also be used. Again, the dense planting excludes weeds and ensures rapid site occupancy. But high planting densities are costly and many of these seedlings may die as competition develops. In drier areas it may be preferable to use lower density plantings to ensure adequate water is available for each tree as it develops.

Low-density plantings may also be useful if large areas of degraded land must be restored but resources are limited. Observations of isolated trees in vacant fields suggest these trees often attract seed-dispersing birds. The birds frequently deposit seeds around the base of the tree that germinate and grow into a cluster of seedlings around each tree. Planting isolated trees or tree clusters to act as bird perches could simulate this process and foster successional development

over large areas, albeit at the expense of much slower rates of recovery.

Species Richness

The numbers of species that should be included in these plantings can vary. As noted above, commercial plantings established by industrial plantation owners generally use a single species. Reforestation carried out to support biodiversity conservation usually involves the use of a much large number of species. The actual number depends on circumstances. In landscapes where large numbers of forest remnants remain close by (i.e., the dispersal distances are short), only a modest number of species might need to be planted to initiate a succession because natural colonization by other species will take place over time and enrich the planted area. In these circumstances a dense planting of mostly short-lived early colonizer species may be sufficient to accelerate the successional process and only a small number of species might need to be used. Likewise, if the number of canopy species in the natural forest is low, it may be possible to replant most of these species and rely on successional development to restore understory diversity (*see* Case Study 2). In both cases the recovery process is initiated by planting but is completed by natural successional processes. Interestingly, the same colonization process can occur within simple plantation monocultures (Figure 3). The value of such plantations as wildlife habitats is likely to be substantially enhanced by this understory.

A different approach is needed where remnant vegetation is not close by or seed dispersal might be limited due to the absence of appropriate wildlife species able to carry seed to the deforested site. In such cases a much higher proportion of the total plant diversity may need to be brought to the site to achieve any degree of biodiversity within a useful time period. Under these circumstances ecological restoration might be difficult to achieve.

Figure 3 Native tree seedling colonization in the understory of a tropical hardwood plantation monoculture in northern Australia. The plantation is within 200 m of natural forest and its presence has catalyzed the recovery of substantial plant biodiversity at the site, with permission from J. Frin.

A common difficulty in all of these circumstances is that seed dispersers such as birds may distribute weed species as well as native species. All restoration programs, but particularly those relying on successional development to achieve ecosystem diversity, may therefore need substantial weed control before full site occupancy by the original species is achieved. Even then, tending may be needed for some years until canopy cover is achieved and the new community is less prone to colonization by weeds.

Ecosystem Recovery After Reforestation

Random plantings of a variety of trees will not necessarily restore the ecosystem that was once present at a site. These species must be able to reproduce and regenerate and the wildlife community must be reintroduced as well to re-establish trophic networks. Some plant species may require particular soil or microclimatic conditions to germinate and grow and will not become established from seed dispersed into a newly forested area until these conditions are met. Other species may need particular regeneration niches to reproduce after they have been planted at a site. For Species A to successfully colonize or reproduce at a site, Species B may need to be established first. In most ecosystems such rules of assembly are only poorly understood. What is clear, however, is

that many animal species (including insects) are part of this development process because of the mutualistic partnerships they often form with plants that enable processes such as pollination and seed dispersal. Species A (a plant) may require Species B (a bird) for pollination and that, in turn, also needs Species C and D (plants flowering and supplying food at other times of the year). Ecosystem restoration is dependent on the formation of these complex trophic networks and interactions.

It is commonly assumed that animals will colonize new plant communities once successional processes have created appropriate habitat conditions. Like plants, animals may be classified as early colonists, tolerant of a broad range of habitat conditions, or later colonists that have more specialized habitat requirements that only develop when the succession has reached a relatively mature phase. A commercial plantation established using a single exotic tree species is likely to be much less attractive to many wildlife than a spatially and structurally complex new forest of native tree and undergrowth species. Likewise, the structural features of an old-growth forest such as thick litter layers, hollow trees, or rotting logs on the forest floor may take years to develop following restoration. These might need to be artificially simulated to foster the re-entry of particular wildlife (e.g., by dragging logs into a restored area or using nest boxes).

Wildlife from early successional stages is often able to recolonize restored forests relatively quickly. But two factors can limit the extent to which recolonization occurs more generally. Some wildlife, especially those with habitats in mature or old-growth forests, are unable to cross degraded landscapes lacking trees. Restored forests not linked with natural forest remnants may therefore be permanently deprived of such animal species unless some means can be found to overcome the blockage. A second limiting factor is that small forest remnants in degraded landscapes often contain only a subset of the original species formerly present. Vertebrates appear to disappear more rapidly from fragments than do plants whereas top-carnivores and large-bodied animal species in particular have large spatial requirements, making them especially sensitive to forest fragmentation. This means that recolonization may be impossible unless these species are brought in from more distant geographic locations. Wildlife recolonization may also be limited by predatory behavior or competitive relations between various animal species. Naturalized exotic predators such as foxes or cats represent a particular problem.

Many threatened or endangered wildlife species will require special habitat conditions. Where the threat to these species is from naturalized exotic predators, these new habitats might be most easily restored on offshore islands, which ensures the exotics are excluded (that is the isolation effect noted above becomes an advantage). This is considered in Case Study 3. However, a dilemma can then emerge over whether the specialized habits required by the endangered species means other species are discriminated against. Is ecological restoration the goal or is a more specialized and restrictive objective such as maximizing the population of a particular species through some form of rehabilitation more appropriate? Answers to such questions obviously depend on local circumstances.

All natural ecosystems are subject to disturbances and the well-known intermediate disturbance hypothesis suggests

ecosystem diversity reaches an optimum when the frequency of disturbances reaches some intermediate level. This means that the initial protection offered to reforestation projects to prevent further degradation must be relaxed at some stage to enable normal ecosystem processes to occur. There are few guidelines to describe how this should be carried out. The disturbance regime that produced degradation is different from that fostering diversity but the nature of these differences is rarely understood. For example, at what point can fire be allowed to occur? Indeed, when should fire be actively encouraged? And how intense should this fire be? These issues will not be important in reforestation projects where enhanced productivity is the objective but might be crucial to the ultimate success of many restoration projects.

Choosing Areas to Reforest

Reforestation is expensive and takes time. It is rarely possible to quickly reforest large areas at once and strategic planning is needed to identify priority areas where the early benefits from reforestation can be maximized. When reforestation is being carried out for commercial reasons, the location of a reforestation area will be dictated by markets and soils. The best locations will be those where transport conditions are shortest and where productivity is highest.

When the purpose of reforestation is to restore biodiversity to a degraded site, the choice is more complex. Possible locations are outlined in [Table 2](#). Common targets are degraded areas within forested nature reserves or the buffer strips around such reserves. In these areas the task is to restore the ecological integrity of a particular site and hence that of the larger reserve area as well. Since colonization distances are likely to be short, there is a high probability of success if disturbing agents can be removed and weeds can be eradicated.

Another common target is to establish corridors linking forest fragments still remaining in a formerly forested landscape. The purpose of this is to foster connectivity between forest fragments as well as to increase the area of habitats for species in these landscapes. Some have argued that narrow corridors are more likely to be the areas of increased predation rather than a means by which wildlife species movement across the landscape and genetic exchange are enhanced. But others

have argued that any increase in spatial heterogeneity should be beneficial and the advantages would seem to outweigh any disadvantages provided corridor widths are not too narrow.

Key targets for many restoration projects are the habitats of particular species such as those whose populations have declined or are endangered by other predatory species. This presumes, of course, that these habitat requirements are known. In the latter case, offshore islands have been especially useful areas to use because they are of sufficient size to contemplate eradicating such predators and to be assured that recolonization will not occur. Encouraging results have been reported from New Zealand (*see Case Study 3*).

Many reforestation programs are carried out because of the improvements in ecological services rather than because they restore biodiversity. For example, stream-sides are often degraded by grazing cattle that cause bank erosion and slumping. Reforestation can stabilize these areas and the vegetation can act as a filter by trapping topsoil erosion. Such reforestation can also have conservation benefits, of course, since these areas are often the focal points within drier landscapes for much wildlife activity. Reforestation of upper or lower watershed areas may be necessary to improve water logging or salinity and, again, indirectly improve landscape biodiversity. Some of the most innovative and impressive restoration has been carried out at mine sites. These areas are intensively degraded and can cause serious pollution problems (e.g., heavy metals, acid drainage, salinity) in large areas of the catchment below the mine site even though the size of the actual mine itself may be small. Mine site restoration usually requires careful stockpiling and respreading of topsoils but the large expenses of doing this are commonly only a small percentage of total mine expenses (*see Case Study 4 and Case Study 5*).

Specialized Conditions or Sites with Particular Problems

Some sites have particular problems. This might be because of the degree of degradation suffered (compacted or infertile soils, saline areas, waterlogged sites) or because of the stressful environmental conditions present (e.g., unstable soils, windswept, or cold mountain areas, desert areas). A variety of techniques

Table 2 Priority areas for reforestation

<i>Location</i>	<i>Reason</i>
Degraded areas in or around nature reserves	To remove weeds and restore ecological integrity to the reserve
Corridors between forest fragments or reserves	To improve connectivity between habitats and metapopulations
Habitats of endangered or threatened species	To increase the populations of these species
Offshore islands	Because islands may be areas free from naturalized weeds or pests that would otherwise preclude restoration on a mainland
Riparian areas	To protect streambanks and because riparian areas are often centers of wildlife activity in many drier landscapes
Upper watersheds	To stabilize catchments, prevent erosion, and improve downstream water quality
Lower watersheds	To lower water tables or reduce salinity
Mine sites or other severely degraded areas	To overcome the extreme degradation that may have occurred and to prevent these areas from becoming erosion sources or sources of toxic leachates
General landscape matrix between forest fragments	To increase landscape heterogeneity and to provide "stepping stones" between natural forest remnants

have been developed to deal with many of these conditions, including ripping and plowing, fertilizing, using drains or mounds to allow more tolerant species to become established at waterlogged or saline sites, etc. In some cases mycorrhiza and soil fauna such as earthworms must be reintroduced as well as nitrogen-fixing plants to promote nutrient cycling. Sites in extreme environments such as mountainous or exposed areas are particularly difficult. Sometimes tolerant exotic species can be planted to facilitate the later establishment of native species. But the survival rates of planted seedlings in especially severe environments can be very low. This raises the question of whether it is worth even attempting to restore severely degraded ecosystems or whether a better return on the resources to be invested might come from restoring only moderately degraded landscapes. In such cases a balance must be struck between what is biologically possible and what is economically feasible.

Socioeconomic Issues

Ecological restoration can be difficult because it requires detailed knowledge of the autecology of a number of species and of the processes of successional development. But the economic and social issues confronting many reforestation projects are equally complex. One of the most difficult to overcome is the financial cost of reforestation. Not only is reforestation expensive but it has an opportunity cost. Some landholders will be willing to undertake reforestation to conserve biodiversity but most will need the financial benefits of reforestation to exceed the direct and indirect costs of carrying it out (*see* Case Study 6). An additional problem is that, unlike most agricultural crops, tree growing takes many years to produce a financial return whereas most of the costs occur in the first few years. These cost issues will dissuade many landowners from undertaking reforestation.

A second issue concerns the type of reforestation carried out. Many landholders will use simple monocultures because these are the easiest to manage but monocultures usually offer only modest biodiversity conservation benefits. The task is to find methods of reforestation that generate financial benefits for landholders as well as conservation benefits. There are, in fact, several possibilities. These include surrounding monocultural plantations with species-rich buffer strips or planting different species in different parts of the landscape according to the environmental conditions at each site thereby creating a heterogeneous landscape mosaic. Another possibility is to establish polycultures that include a number of tree or understory species (*see* Case Study 2). These can be financially profitable as well as creating structurally complex habitats suitable for many wildlife species (Lamb, 1998, Lamb, 2011).

Socioeconomic problems increase when reforestation is attempted at a landscape scale. Most conservation benefits, including biodiversity conservation, are only generated when reforestation is carried out at this scale. But reforestation at a landscape scale usually requires dealing with a large number of stakeholders. The most obvious are landowners, leaseholders, or people who have some traditional claim to the land (although that claim might not be recognized by the state). Others may be downstream water-users, conservationists or simply the general public. As noted earlier, these various

groups may view degradation and the desirability of reforestation in quite different ways. This means those proposing to undertake reforestation on a large scale must resolve (1) where reforestation is to be done, (2) how much is to be carried out, and (3) what types of reforestation are to be used at particular sites. Experience in many places suggests this is best done by involving all stakeholders in the planning and management process, including those in a weak bargaining position and those with little political power. In this way, all interests can be protected from the beginning. Some form of educational program may also be necessary to allow the various stakeholders to see the reasons for the project and the benefits it may have for themselves (e.g., perhaps in employment opportunities) as well as for the community as a whole. Likewise, some form of incentive or compensation may be needed to persuade the participation of landholders controlling in critical areas within the landscape. One way in which this might be done is to pay for the environmental services generated by reforestation (e.g., watershed protection, carbon sequestration, biodiversity protection). If this collaborative planning or various forms of compensation do not occur there may be a high risk of continued disturbances and further degradation.

Conclusion

Although, deforestation continues globally, reforestation of degraded lands and forests can help protect biodiversity and restore it to landscapes from where certain species have disappeared. There is a wider variety of silvicultural techniques available than is generally supposed although more work is needed to develop techniques that generate both financial and conservation outcomes. One of the key tasks is to find ways of making these options attractive to landholders at particular sites and to coordinate reforestation activities across degraded landscapes to foster biodiversity conservation. Although the survival of many wildlife species will be assisted by reforestation some species may not benefit, at least in the short term. These include forest-dependent fauna with specialized habitat requirements and large home ranges. Such species will continue to depend largely on natural forests although reforestation within and around such areas will be beneficial.

Case Study 1: Forest Restoration by Transforming Monospecific Conifer Plantations in the UK

Not all forms of reforestation involve re-establishing trees on largely deforested land. In parts of the UK reforestation now also involves converting conifer forests containing a single dominant tree species to more diverse species-rich forests. Much of the reforestation effort during the twentieth century in the UK was aimed at establishing timber plantations of fast-growing commercially valuable pine or spruce species. Many of these species were exotics such as Sitka spruce or Norway spruce. In recent years managers are seeking to transform these structurally simple forests to more complex mixtures of softwood and native broad-leaved species that have a greater biodiversity and conservation value. Where landholders are interested, the first step, in the process is to identify the

appropriate type of native forest that might be grown at the site. This is usually based on surveys of any natural woodlands in the surrounding landscape together with historical records. The second step is to identify those sites with the greatest opportunities for conversion. These might be those where the existing forest already has a good representation of specialist woodland ground flora, where there are existing patches of seminatural forest nearby able to act as a source of colonists or sites where the location and size of the new forest will enable it to make a contribution to regional conservation goals.

The preferred method of conversion is to rely on natural regeneration by native species and this has been favored by manipulating the existing tree canopy. In some cases this has involved line thinnings and in other cases by clear-felling small patches. Thinning is expensive and the extent to which this is being carried out often depends on the availability of markets for the timber being produced. The native species able to take advantage of the improved canopy gaps have been either present in the forest understory or have colonized from nearby woodlands.

The objective of reforestation in the original commercial timber plantations in the UK was to create a harvestable timber resource. By contrast, the objective of this particular reforestation program is to gradually convert the plantations of largely exotic conifer species to deciduous broadleaved or mixtures of broadleaved and native conifer forests that conserve both local and regional plant and animal biodiversity. Results so far have been encouraging (Harmer *et al.*, 2005).

Case Study 2: Mixed-Species Plantings in North Queensland, Australia

Several types of reforestation have been carried out on cleared land formerly occupied by rainforest in northern Australia. The government Forestry Department initially established monocultures of various species including native high-value timber trees. The normal rotation of these was around 40 years although some have been retained for up to 60 years. Over time many of these have been colonized by species from nearby natural forests transforming these simple plantations into very diverse forest communities (Figure 3). In other cases farmers have established mixed-species plantings of mainly native high-value timber trees with the objective of generating a future cash income while also contributing to region conservation goals. Most of these have used less than ten tree species. A third approach has been to reforest certain areas with the objective of restoring former forest ecosystems without attempting to create a timber resource. These have used an average of 50 tree species. Most of these plantings, with the exception of the old plantation monocultures, are less than 20 years old and are yet to develop habitats suitable for wildlife with specialized habitat requirements. Nonetheless, all have acquired high levels of plant and animal diversity. The extent of this diversity and the types of species present has depended on the types of plantings used, their age, and their location in the landscape relative to the remaining areas of natural forest. Not surprisingly, the species-rich plantings established to restore the natural

forest have generated faster rates of recovery than the mixed-species timber plantations. Perhaps more surprising has been the very high levels of diversity found in the older monocultures with species-area curves showing more than 30 plant species present within 300 m² (Keenan *et al.*, 1997; Erskine *et al.*, 2007).

Case Study 3: Restoration of Habitats of Endangered Biota in New Zealand

Sometimes specific forms of reforestation are needed to conserve particular biota. This is the case on the island (or minicontinent) of New Zealand which has a unique biota but many of which have become endangered since the arrival of humans. In the case of birds, for example, 48% of species have been lost in the past 200 years because of the introduction of predatory and browsing mammals. Even in protected areas, attempts to maintain populations of some presently endangered species are difficult because of the difficulty in controlling predatory species over large areas. New Zealand has many offshore islands that were once part of the mainland (and consequently contain many mainland species). Although a number have been deforested or degraded, they are potential safe havens for endangered species since it may be feasible to eradicate predators and browsers over these smaller and more isolated locations. This has fostered a shift in attitude from trying to simply preserve species to restoring their preferred habitats.

The first step has been to mount a vigorous campaign to eradicate exotic species such as cattle, goats, rodents, and cats from the islands. Although the larger grazing animals are comparatively easy to remove, thereby enabling forest regeneration, it has only been in more recent years that techniques for eradicating rodents have become successful. In many situations this alone has led to improvements in habitat quality. The second step, on islands where deforestation has been severe, has been to replant trees and shrubs to re-establish appropriate habitat conditions. Where populations of target species are already present, these two steps have often been sufficient to enable them to survive and flourish. In other cases it has been necessary to translocate animals from the mainland to establish new breeding populations. The success of the program has been followed by similar attempts to restore biodiversity to islands of forest on the New Zealand mainland. These are the patches of degraded forest land within largely agricultural or otherwise severely disturbed landscapes.

The objective of these programs has been quite specific; it is not to necessarily restore the original forest ecosystems but rather to seek to re-establish sufficient of the original ecosystems to enable the survival of nominated species or communities. This goal acknowledges that restoration may never be complete because some exotic organism may always be present or because knowledge of the original system may always be incomplete. In the New Zealand context, however, the goal is a way of ensuring the protection of a significant proportion of the country's biological heritage (Towns and Ballantine, 1993; Saunders and Norton, 2001).

Case Study 4: Reforestation after Mining Tropical Forest Lands in Brazil

Mining causes complete degradation of an ecosystem and perhaps represents one of the greatest challenges to those interested in restoration, particularly if the site was previously occupied by a biologically rich tropical rain forest. The Trombetas bauxite mine in Amazonia has an annual reforestation program of 100 ha. Following mining, the sites are leveled and stockpiled topsoil is spread back over the area to a depth of 15 cm. The site is then ripped and replanted using seed, stumps, and seedlings. About 70 species are planted at a density of around 2500 trees per hectare.

Studies carried out in an area that had been replanted 10 years earlier found forest development had been rapid. A number of plant species had colonized the site from the adjoining rain forest. After 10 years these represented 60% of the total number of woody species present and the site contained around 50% of the species present in the adjoining, undisturbed forest. Some areas had rather sparser forest cover than others and the colonization process was less vigorous in these, most probably because of the presence of grasses in the understory. The density and composition of the understory developing beneath the planted trees were related to the overstory basal area and topsoil depth but negatively related to the distance from the undisturbed forest. Primary forest species were able to colonize up to 640 m although most colonists had smaller diaspores. Most of the colonists in the more open sites with grass were early pioneer species.

Surveys of wildlife found low densities of birds but high densities of bats. Most of the bird species were representative of secondary forests and are unlikely to have carried many seeds from the undisturbed forest nearby. However, the bats included several important seed dispersers which feed on a variety of tree species and are able to carry seed over large distances. A number of other mammal species (e.g., opossums, deer, agouti, and armadillo) were also observed within the study site.

It appears that a dynamic and sustainable successional environment has been established in a much shorter time than it would otherwise take to occur. This was due to the respreading of topsoil which contained a number of important tree species and the choice of trees planted in the original planting program. The program was less successful where tree survival or growth allowed grasses to become established and at these sites the successional process may be rather longer (Parrotta *et al.*, 1997).

Case Study 5: Reforestation after Mining in Temperate Forest Lands in Australia

The *Eucalyptus marginata* forests in the south west of Western Australia are extremely diverse and the region contains around 780 plant species. Much of this diversity is contained within the understory plants rather than in the tree overstory. The area has a Mediterranean climate with hot dry summers and cool wet winters. Mining started in the area in the 1960s. As in Brazil, bauxite is extracted using open cut mining. Before mining, the topsoil and overburden are removed in two layers

(0–15 cm and 15–80 cm) and stored. After mining, the topsoil is replaced in the same sequence and the site is deep-ripped to break up the compacted mine pit floor. Logs and rocks are also added to provide fauna habitat. Replacing the topsoil re-introduces some species having dormant seed stored in the topsoil. Other plant species are re-established using a combination of direct seeding and by planting seedlings. Those reintroduced as seedlings are species with scarce seed or with seed that is difficult to germinate and which need special propagation methods. Most of these species are introduced at more or less the same time. Of the 140 species usually found at any particular site about 28 species are reintroduced in topsoils, 78–113 species are brought back using seed and the remainder are planted as seedlings. Sufficient seed or seedlings are used to produce a tree density of around 1300 trees per hectare. No attempt is made to reintroduce wildlife since these are able to colonize from nearby intact forest that was not disturbed by mining.

These reforestation methods have been developed and refined over a long period and there is now evidence that they generate productive and structurally diverse forests containing most of the original plant and animal diversity. The species restored include herbivores, detritivores, nectivores, insectivores, and carnivores although some wildlife species are still limited by the absence of habitat features such as hollow-bearing trees or rotting logs that will take some time to develop. The new communities are adapted to the wildfires that normally occur in these forests and fire-adapted species are able to regenerate naturally (Koch and Hobbs, 2007).

Case Study 6: Reforestation of Degraded Lands in Nepal

Any form of reforestation must be compatible with the needs of landowners. In Nepal, forests are an integral part of the farming system with leaves and grass being used for fodder and animal bedding. Such material is also used in compost to maintain productivity of agricultural lands. Timber is regularly harvested for fuel.

Some parts of the middle hills of Nepal have been highly degraded over time because of intensive harvesting. However, externally sponsored attempts to encourage land users to reforest have not always been successful. If there is forest near villages, there is commonly little interest in forest protection or tree planting although indigenous management systems (primarily to define user access rights) for these forests may exist. By contrast, where there is a severe shortage of forest products and any remaining forests are more distant, there is likely to be a genuine interest in forest development activities and well-developed indigenous management systems for the remaining forests. These systems are likely to have biological objectives (e.g., rotational cutting) as well as simply defining user access rights. That is, interest in reforestation depends on the perceived need of land users and not on an external perception that forest degradation or a loss of biodiversity has occurred.

Indigenous management systems can foster reforestation under certain conditions and some areas of private farmland in Nepal now have more forest cover than in earlier years.

However, this does not invariably occur. For example, larger trees may be protected but grazing beneath these may lead to a failure of regeneration. Likewise cutting of smaller trees for firewood may be tolerated whereas the larger trees are saved. A particularly difficult situation can be where a cash market for forest products develops. In such cases poor people can succumb to the temptation to cut firewood, often at night, to sell the next day. Indigenous management systems must be very strong to resist such pressures.

Tree planting has been carried out at particularly degraded sites. The most successful reforestation has been with pines, although broad-leaved species are more valued by villagers as leaf fodder. Manipulative trials with young pine plantations have found that many broad-leaved species can also then regenerate from suppressed stumps and root stocks or seed once the sites are protected. This natural successional development increases the silvicultural options available, giving local communities greater flexibility in determining their preferred forest management strategy. It is also possible to thin the young pine stand and enrich it using other broad-leaved species that might otherwise be difficult to establish. This, too, increases the options available. Reforestation of degraded sites and the development of indigenous management systems may not always take place without some outside intervention. Once benefits start to accrue to land users, however, neighbors are often quick to pick up the ideas and follow the example. At this point it is important that government agencies who might legally own the land are cautious in imposing rigid bureaucratic controls within which the new forests must fit. For example, allowing someone from outside the user group to harvest resources from the new forest could easily unleash a surge of unregulated harvesting, leading to a renewed degradation (Gilmour, 1990; Gilmour *et al.*, 1990).

Glossary

Active restoration Requiring manipulation by humans for successful colonization and/or establishment of organisms and ecosystem functioning.

Functional diversity Having all of the functions required for maintenance of ecosystem processes, but not necessarily all of the species richness.

Functional redundancy, functional similarity Having species that may be substituted because their contributions to ecosystem processes are similar or overlapping.

Passive restoration Relying on natural successional processes for restoration after the stresses that caused the disturbance have been removed.

Reclamation A revegetation or land management goal that includes a lower diversity of species and may include substitutions by introduced species.

Reference area An undisturbed or natural area chosen to compare with a restored site to determine the success of restoration.

Rehabilitation Creation of an alternative ecosystem following a disturbance, different from the original and having utilitarian rather than conservation values.

Restoration The manipulation of organisms and ecological processes to create self-organizing ecosystems that resemble predisturbance structure and functioning and promote conservation of biodiversity.

Restoration Goals: Conservation and Biodiversity

Conservation of biodiversity is the central goal of most restoration efforts and ranges from reintroductions of individual species of rare plants and animals to efforts to reintroduce a high diversity of species (Jordan *et al.*, 1987, 1988; Bowles and Whelan, 1994; Falk *et al.*, 1996). Restoration may be defined as the manipulation of organisms and ecological processes to create self-organizing, sustainable, native ecosystems as integral parts of the landscape, as much as possible as they existed before disruptive human disturbances. Where propagules of native organisms are remnant, restoration may require reintroducing ecosystem functions such as fire or hydrologic regime to enable natural recolonization and recovery processes. Re-creation of a close replica of a previously existing ecosystem type is increasingly difficult in a world with a growing human population, considering fragmentation and limits to dispersal of organisms; global invasions of exotic species that cause large-scale replacement and even extinction of native species; air, water, and soil eutrophication; and habitat loss by land conversion to urbanization and agriculture. Even nature reserves and parks suffer from visitor overutilization and other impacts, and restoration coupled with more careful management is required to preserve the original flora and fauna.

There are limits to restoration whether biodiversity or functioning of the ecosystem is concerned, but restoring all of the species richness that was originally present on a site is usually more difficult than restoring similar functioning. The reasons are that many rare species are difficult to propagate, their basic biology has often not been studied, they have lost genetic diversity, and their propagules are limited due to habitat loss. They are also less likely to be chosen for many

kinds of restoration because they are more expensive to reintroduce and they contribute relatively little as individual species to ecosystem functioning. On the other hand, abundant species are generally better known ecologically, and in some cases, individual abundant species will regulate ecosystem functioning. Restorationists more often focus on reintroducing the abundant plant species or the “matrix” species to initiate succession and recovery of disturbed lands. Reintroducing dominant species enables a recovery of major functions and most of the vegetation vertical and horizontal structure. For instance, John Ewel showed that low-diversity replanted (but not restored) tropical forest in Costa Rica may have similar levels of soil nutrients, organic matter, and nutrient loss, compared to natural forest, but will not have the same conservation value for species preservation.

Additional limits to restoration of diversity are economic, political, and social. Restoration for the intrinsic value of nature, with its complement of biodiversity, often includes participation by laypersons who wish to see nature returned to a state they remember from years ago or that was documented in historical texts or anecdotally. Lesser goals than restoration include reclamation or rehabilitation (National Academy of Sciences, 1974), which have utilitarian values and less emphasis on conservation and biodiversity values. Reclamation may include a less diverse mix of species and exotic substitutions, while rehabilitation is simply to make the land useful again and may produce an alternative ecosystem, such as turning a forest into a pasture.

In this article, we will examine the possibilities and the limits to restoration of biodiversity. Different species have different limits and require different approaches for restoration. We divide the discussion into restoration of plants, animals, and soil microorganisms. This is admittedly an overly simplistic approach, as they all interact. However, points of

overlap among the groups are brought out numerous times within each section. The division is logical in that the three groups require different degrees of active or passive restoration, depending on the level of disturbance of a site (Figure 1). The kinds of disturbances that require restoration are varied. They range from drastic alteration of the ecosystem, such as surface mining or other construction projects that remove the topsoil; to abandonment from agriculture that leaves soil nutrients and a largely weedy seed bank; to invasion of natural vegetation by exotic weeds that leaves the soil intact but depletes native biodiversity; to alteration of certain ecosystem functions such as fire cycle or hydrologic regime; to extirpation of individual species with no other associated impacts to the physical habitat. Plant introduction and management are central to restoration projects where disturbance has caused vegetation removal or weed invasion. Where plant propagules remain or are readily dispersed, as after abandonment from agriculture in the northeastern United States, passive restoration may suffice. For animals, habitat may be created by manipulating the structure of the plant community, with the hope that the animals will recolonize. This has come to be called the "build it and they will come" hypothesis (see article by Palmer *et al.* in *Restoration Ecology*, Vol. 5, 1997). However, recolonization may be restricted by fragmentation, lack of corridors, or lack of propagules, so reintroduction of the animal into restored or intact vegetation may be needed.

For microorganisms, passive restoration is generally the rule in contrast to higher organisms that may be purposefully reintroduced. Very few species of microorganisms that are members of natural ecosystems are cultured, so they are not even available for restoration purposes. The exceptions are symbionts (N-fixing bacteria, mycorrhizae) that are used routinely in agriculture and reforestation, but less often in restoration. All the other taxa that contribute to belowground functioning of native ecosystems are never or rarely cultured, including soil saprotrophic fungi, bacteria, nematodes, and other soil micro- and mesofauna. For all of these groups, we must learn how to manage the soil to promote their recolonization and to understand the distances from which they may be able to recolonize. In addition, there may be 1000s of species of microorganisms even in 1 cm³ of soil. So the argument must be made whether all these species can or should be reintroduced. Many ecologists argue that there is functional redundancy among so many microbial species and that a minimum number of functional groups rather than a minimum number of species are required for restoration of ecosystem functioning.

The goals for restoration may vary for these three groups of organisms. For plants and animals, species diversity concerns are high, but for soil microorganisms, functional diversity is more often expressed as the concern. The limits and possibilities for restoration of diversity vary for the three groups, and the discussion below will expand upon these topics.

Figure 1 A comparison of active and passive restoration. Active restoration requires various degrees of human intervention, depending on the degree of disturbance, while passive restoration only requires removal of the stresses that caused the initial disturbance, such as grazing or pollution, followed by natural recovery processes.

Restoring a Diverse Plant Community

To improve plant species diversity, the kind of revegetation or vegetation management is determined by the degree of disturbance. These form a gradient of disturbance types and recovery possibilities that require the entire range of active to passive restoration. Heavily disturbed sites such as surface mines need to have all species reintroduced, whereas slightly disturbed sites may be missing certain species that are not adapted to the new postdisturbance conditions, such as alteration of fire regime. Other sites may require weed control to increase native species diversity. There are no examples of severely disturbed sites that have been restored to their original complement of species. This may be related to the high costs involved, the changed environmental conditions, and the sheer impossibility of artificially reintroducing a large number of species. As richness increases in more productive habitats, the probability of reintroducing even a majority of the species diminishes. One of the best examples of attempts to restore a diversity of species comes from bauxite mining in

southwestern Australia, where 80 species or more may be included in the seed mix. However, the adjacent undisturbed jarrah (*Eucalyptus marginata*) forest may contain more than 200 species. In Wyoming sagebrush–grasslands, mining reclamation regulations are not as strict, and typically only 5–10 native species are planted in an area that may have 50 or more naturally occurring (Figure 2). The dominant rather than the rare species are typically chosen for revegetation, and the long “tail” of rare species that typifies a dominance–diversity curve for natural areas is missing (Figure 2). Reclamation and restoration both generally create communities of a few abundant species but few rare species, whereas undisturbed communities may have the same few abundant species, but in addition will have many rare species.

Limits to Restoring a Diverse Plant Community

The reasons for omitting the many species that form the rare species tail in Figure 2 are many. Seeds or other propagules must be collected locally for the restoration to reflect the local

Figure 2 Dominance–diversity curves for reclaimed and natural vegetation in Wyoming sagebrush–grassland. The long tail of inabundant species found in natural vegetation is seldom reestablished in revegetated areas.

genetic populations, but these are typically not available unless the project is planned well in advance, usually two growing seasons, and the seeds are collected specifically for that project. Collecting native seed is becoming a large industry but it is unusual to have all the species available on the open market at the time they are needed, and even rarer to have the seed collections from local populations (see chapters in Falk *et al.*, 1996).

Loss of genetic diversity and lack of local ecotypes are also a limitation to restoration. Where local extirpations have occurred, the nearest populations may no longer have all the genetic diversity of the original, and restoration in the true sense of restoring genetic as well as species diversity is no longer possible. Locally selected ecotypes have the "home team advantage" of being better adapted to local conditions and also avoid problems of outcrossing and hybrid depression with remnant native individuals (see article by Montalvo *et al.* in *Restoration Ecology*, Vol. 5, 1997). Additional discussion of genetic issues is in the section on animal restoration.

Once the appropriate local seeds or propagules have been collected, there is little information on seed dormancy and propagation of most species. The emphasis on conservation biology in the past decade has resulted in increased concern for research on rare species, and information on propagation, microenvironment requirements, reasons for disappearance, interactions with pollinators and other species, and so forth have enabled restorationists to include rare species in revegetation plans. More often, restorationists work with relatively unknown species and must begin research anew for each species, as, for example, the work on restoring the endangered *Amsinckia grandiflora* (see chapter by Pavlik in Falk *et al.*, 1996). Lack of biological information on species translates into practical economic limitations. Most often, only the species that are best understood with the most available propagules are used.

Once germination and propagation requirements are understood, the plants must go into a field setting that presents a whole new set of problems. Different species germinate at different times and have different growth rates, so some will

never emerge from certain seed mixes. The northern Great Plains of the United States are dominated by *Bouteloua gracilis* in the coal mining regions, but this has proven to be one of the most difficult species to reestablish for mining reclamation. It is a slow-growing, late-germinating, warm-season grass, but when it is seeded as part of a mix of native species, the cool-season grasses germinate first, grow quickly, and dominate. Reclamationists have devised numerous methods to reestablish short-grass prairie, such as alternating seed drill rows or planting *Bouteloua* seeds a year earlier. However, the most important consideration for companies that have spent millions of dollars on earth-moving is to stabilize the soil, rather than to establish high levels of diversity that are not required by law in any case. Preventing soil erosion is the first goal, and the mines of this region use a fast-growing native plant mix that reduces the establishment of slow-growing species. The goals of soil stabilization using productive plant species and establishing a diverse mixture are often at odds (Figure 3).

Reestablishing the full complement of species may require reintroduction in stages, as shown in examples from the tallgrass prairie. When Robert Betz began prairie restoration in the late 1960s at the Fermi Lab prairie in Illinois, he quickly learned that the dominant native grasses could be readily established from seed. He used the grasses to form the matrix of vegetation, followed by later introductions of the less common forbs. These forbs could not colonize naturally into the restored grassland because of the high density of grasses, but could be hand planted. Thus Betz was able to restore 116 plant species to the Fermi Lab prairie, but only by expensive hand labor. Similarly, the Curtis Prairie in Wisconsin, the oldest restored prairie, was initially planted during the 1930s, but plants have been continually introduced since then (see chapter by Cottam in Jordan *et al.*, 1987). Their survival has been monitored, and they now contribute to the most diverse tallgrass prairie anywhere. The Curtis Prairie has over 300 species in 10 acres, more than any remnant natural prairie.

Competition from invasive plant species is another important limit to restoration of diversity. The invasives may be

Figure 3 The relationships among soil fertilizer level, plant species richness, plant productivity, and soil erosion. The trade-off for using fertilizer to promote high initial rates of plant productivity to reduce soil erosion is a loss in diversity.

weeds that are part of the successional process, but a more difficult problem than early seral weeds are those invasive plant species that persist and cause vegetation type conversions. In this case, the major restoration activities involve mowing, fire, or selective weeding to remove the offensive species, planting or managing for regrowth of natives, and then continual management to keep the invasives from becoming dominant once again (see chapters in Allen, 1988; Falk *et al.*, 1996). Such activities have been undertaken in Florida, where *Schinus terebinthifolium* and *Melaleuca quinquenervia* dominate wetlands, Hawaii, where exotic perennial grasses and *Myrica faya* have replaced native vegetation, California, where Mediterranean annual grasses have replaced native perennial grasslands, and in many other sites worldwide (Lee, Richardson in *Encyclopedia of Biodiversity*).

Poor, toxic, eutrophied, or erosive soils also impair the conservation value of restored communities. Any practice that changes the soil from its original physical or chemical state will also change the plant species composition. An example comes from the china clay mines in England, where the mining refuse is high in sand. Local plants are poorly adapted to the droughty and nutrient-poor sand, so strand plants are imported for revegetation (Bradshaw and Chadwick, 1980). As expected, these artificial strand communities are poor in diversity. However, Bradshaw has documented some relatively high species diversity following natural colonization onto abandoned waste sites, although not as high as surrounding native areas. There is a tendency during revegetation to overfertilize soils to agricultural levels when fertilizer is applied, with expected poor results for native plant diversity. The reason for overfertilizing is usually economic, to promote vegetation establishment and therefore prevent soil erosion, but may also be aesthetic, to please the paying public as rapidly as possible. As shown by the experiments of Tilman, (Tilman in *Encyclopedia of Biodiversity*) overfertilization, especially by nitrogen, will promote the productivity of a few species to the detriment of stand richness (Figure 3). For restoration to promote the natural levels of species richness, the soils must be in their natural fertility condition as much as possible. If erosion is a problem, then other means to control erosion, such as mulch or temporary mechanical barriers, could be used to stabilize the soil and allow the slow-growing plant species to establish within a mixture of fast-growing species.

Improving Plant Species Diversity

Restorationists have used many techniques to increase richness of plant communities when the seed and propagule sources are limiting. Taking advantage of the existing seedbank is a primary one, where the seedbank still exists. Mined land reclamation laws in developed nations often require retopsoiling with fresh topsoil, and many studies document the importance of this source. Certain species still need to be supplemented, as in the case of late seral species absent from the seedbank of jarrah forest in southwestern Australia (see chapter by Bell in Allen, 1988). Jarrah seed is never found in the seedbank, and it reproduces vegetatively after fire in natural communities. It must be reintroduced as nursery transplants for revegetation to be successful. While the seedbank is

an important source of diversity in many kinds of restorations, it is also notorious for harboring a large complement of early successional and weedy species. Bradshaw and Chadwick (1980) have recommended against using topsoil just for this reason, if appropriate weed-free subsoil can be found and amended to support plant growth.

Dispersal of propagules into the restored site is another way to increase diversity that depends upon landscape structure such as proximity of source populations or existence of corridors. In a study of 2- to 18-year-old revegetated, untopsoiled roadsides in San Diego County, dispersal from adjacent mediterranean shrubland more than doubled the richness from 12 planted species to a maximum of 16 colonizing native species. However, dispersal of native species only occurred when the shrublands were adjacent to the highway, and occurred rarely in urban areas of the highway. Reclaimed surface mines in Wyoming that are surrounded by native sagebrush-grassland have a higher richness of colonizing species than, for instance, a revegetated landfill in Staten Island that is surrounded by suburbia (see articles by Bell and by Ehrenfeld in *Restoration Ecology*, Vol. 5, 1997). While dispersal is often limited by vectors in terrestrial habitats, aquatic and riparian habitats typically are recolonized rapidly (National Academy of Sciences, 1992). Water is a very effective medium for propagule dispersal, and these habitats are often not even revegetated, unless the soil needs to be stabilized rapidly in riparian edges or the dispersing propagules include unwanted exotic species.

Vegetation may be replanted to attract animals that are seed dispersers or pollinators and thus may create a positive feedback on the future reproduction and diversity of a site. When a limited suite of species is chosen, the selected species become especially critical. Synthetic grasslands that simulated tallgrass prairie had sufficient diversity and especially structure to attract birds and small mammals (Howe and Brown, 1999). Shrub islands were planted on a surface mine in Wyoming to increase the movement of animals and microorganisms onto a site that was otherwise dominated by grasses (Allen, 1988). The feedback of these shrub species and patterns determined both their mortality and recolonization patterns of additional plant species. In Costa Rica, Karen Holl and Daniel Janzen have shown that tree and shrub "islands" within pastures are critical for attracting animals that disperse seeds and then increase the diversity of the plant community.

Single-Species Plant Introductions

Individual plant species have been reintroduced where they were extirpated, largely because of laws protecting endangered species. Mitigation laws often require transplantation of a rare species from a site that is about to be destroyed to a safe site. For instance, Howald (see chapter in Falk *et al.*, 1996) documents 40 instances where rare species were transplanted for habitat mitigation purposes in California. Of these, only 5 were considered successful, 7 had limited success, 13 were not successful, and others were unknown or ongoing and too recent to evaluate. The reasons for lack of success were varied but included moving plants to sites where they did not exist

previously, having different environmental conditions in the transplant site, or using poor horticultural techniques. Primack (chapter in Falk *et al.*, 1996) planted seeds of 41 species into sites in Massachusetts where they were once known to occur. Of these, only 10 produced seedlings, and only three produced a second generation. In this study, the reasons for failure may have been due to exotic species, changes in natural disturbance regime, and other changes such as anthropogenic nitrogen deposition that causes inappropriately high levels of soil fertility. The relatively few successful transplantations indicate that mitigation transplantation in general is poor policy because the kind of planning and postintroduction management that are required is seldom done in practice. Often little consideration is given to the quality of the habitat into which organisms are being reintroduced. Overall, the reintroduction of one species does little to improve the diversity of a site, but it may be the only option to avoid extinction, provided restorationists and land managers use their best practices.

While many single-species introductions focus on rare species, they may alternatively focus on abundant species. The reintroduction of a keystone species or ecosystem engineer (see Palmer *et al.* in *Restoration Ecology*, Vol. 5, 1997) is one way to “jump start” natural successional processes in a community. Shrubs and trees were removed from rangelands for many years in an effort to increase forage production for domestic animals, but this was short-lived and in the long run promoted degradation of the community because the deep-rooted shrubs changed the nutrient and moisture balance of the entire stand. The reintroductions of *Pistacia lentiscus* in Israel, oak trees in California, or *Artemisia tridentata* in mined lands in Wyoming enable the shrub or tree island effect to reinitiate, building up soil and biotic resources around the transplanted shrub (Allen, 1988). This could potentially result in further increases in diversity as the shrubs enable recolonization of additional species.

Succession on Restored Lands

Restoration depends upon succession to complete the process that was started by revegetation, but succession alone does not always bring us to the goal we wish to achieve. Revegetated lands are not static and can be expected to undergo change in species density, richness, and relative composition. The degree to which they undergo succession varies, depending upon the amount of colonization, initial species complement, and site conditions. Little change in species composition occurred after bauxite mining in the Australian jarrah forest. The site typified Egler’s initial floristics model of succession, where late seral dominants colonize in the earliest stages of succession, because very few species that did not occur in the original seed mix became dominant later on. Sites that were 16 years old appeared structurally different from sites that were 1–2 years old in that woody plants were larger and more evident in the older sites, but most of the same species were present in sites of all age classes. A few surprising species did colonize the older sites, such as a native orchid. In Anthony Bradshaw’s experiments on plants colonizing industrial waste heaps in England, most plants that did not establish appeared to be limited by dispersal and establishment, rather than poor

substrate. The sites were too distant from propagule sources or had dense stands of initially colonizing species that prevented establishment of a diversity of species. The initial floristics model can also be applied to Wyoming, Pennsylvania, and Czech surface mined lands, where the native grasses that dominated early on allowed little colonization of native trees, shrubs, or forbs after 10–30 years.

Even when soil conditions are optimal and sources of propagules for local colonization are available, the initial revegetation treatments will affect long-term successional processes, as shown by recent studies in the journal *Restoration Ecology*. A 30-year-old planted forest that had been severely disturbed by hydroelectric development in New Zealand showed little change over time when 46 native species were planted. The species composition was chosen to resemble the dominants during secondary succession after fire in natural forest, but had only a fraction of the total diversity. However, an even less diverse stand developed when no vegetation was planted, consisting of a stand of exotic *Citrus scoparius* and European grasses. A comparison of planted forest stands on bauxite mines in Brazilian tropical forest showed that planting a low-diversity commercial mix resulted in a low-diversity, but high-productivity forest, while seeding and planting mixes of 70 or more species promoted a diverse, but less productive forest. In all cases, colonization of certain late successional forest species that were not part of the original mix was poor. An interesting contrast comes from the Arctic on the North Slope in Alaska, where more than 100 species of native plants colonized 20 years after planting two native and one exotic grass species over a dozen sites. Thus the productivity and species richness of the initial planted stand will make a large difference in the ability of other species to colonize later. From these examples, and many others in the literature, it is apparent that succession may promote an increase in richness if the planted stand is not so aggressive that it precludes establishment of colonizers. Most often, additional interventions are needed if the desired diversity is to be achieved.

Restoring Animal Diversity

An Introduction to Animal Restoration

Like plant restoration, animal restoration involves reintroducing or encouraging the return of native species to an area or region from which they have been lost. An animal restoration project may involve just a single species, as in the reintroduction of wolves into Yellowstone National Park, or an entire community, as in Augrabies Falls National Park in South Africa, where over 10 species of large mammals have been reintroduced (including black rhinoceros, eland, giraffe, and springbok).

Animal and plant restorations will generally involve the same ecological considerations, and most differences between the two concern a matter of degree and emphasis (Jordan *et al.*, 1988). Save for insects (which represent a challenging form of restoration more in line with promoting microbial diversity), plant restorations generally call for a larger number of species. In terms of ecosystem function, animals have significant roles in restoration as pollinators and herbivores of

the plants. Animal roles in ecosystem function also occur when herbivores alter nutrient cycles and where animals may be “ecological engineers” of the physical environment, such as the contributions to soil function from the digging and foraging activities of earthworms or burrowing mammals (Jordan *et al.*, 1987). In general, animals are more mobile than plants and while plants may disperse widely and unexpectedly as seeds and pollen, a single animal may range over scales that are much larger than that of the restoration project and site. Some of John Laundre’s radiocollared mountain lions from south central Idaho have appeared as far away as Yellowstone National Park in Wyoming and mountain ranges in central Nevada. As a consequence of mobility, restoration sites from the perspective of animals will be open rather than closed systems. In animal restoration, the environs of the restoration site may deserve equal attention. Much attention has been given by all stakeholders to the possible fates and consequences of wolves wandering in and out of their Yellowstone restoration site.

The ecology of animal restoration draws less heavily from theories of ecological succession and more from the ecology of invasions and the ecology of small population sizes (Major, 1989). Plant restorations, as succession, start with an inoculum of plants that initiate a process of changes in species composition that eventually leads to the desired natural community in terms of structure, function, and appearance. This aspect of succession is absent from most animal restorations except in the case of the mostly passive development of an insect and soil invertebrate community that fits and complements the plant community. With most animal restorations, each species enters the community at a very small population size either as an invader or as a reintroduction. Small and alien describes the starting population. Most random introductions of animals to a community fail. Naive animals fall to predators more easily, compete less successfully for resources, often fail to develop or find suitable denning or nesting sites, and sometimes attempt to emigrate from the site. In the absence of preexisting burrows, reintroduced prairie dogs simply roam far and wide in search of colonies. Small animal populations face twin genetic and demographic threats. Small, sexually reproducing populations may suffer inbreeding depression and produce a higher proportion of young with genetic defects. Demographically, small populations may teeter on the edge of extinction. An accidental death, a missed breeding opportunity, or a chance skewing of sex ratios or age distributions may compromise the population irrecoverably.

Animal restoration begins with knowledge of why the species or animal community is currently absent or threatened at the site. Next comes an assessment of whether the site is currently suitable for the animals and an evaluation of what site preparations are necessary to promote success. Then the current status of the animals receives attention to determine the best and likeliest sources of individuals. The animal(s) may be present on site but at low numbers, they may be present near the site or far from the site, or they may only exist as captive populations. Finally, the passive or active restoration of the animals begins with appropriate considerations of how to manage and monitor the project’s success. We will briefly examine each of these steps.

Reasons for the Absence of an Animal or Animal Community from a Site or Region

Habitat fragmentation or changes in land use may reduce or eliminate particular animal species, subsets of species, or entire taxonomic groups of animals from an area. For instance, most animals associate with particular types and structures of vegetation. When altered, by livestock grazing or agriculture for instance, some of the original animals disappear as they cannot find food, nesting, or denning sites or they may be excluded by changing intensities of competition or predation from other animals more suited to the new circumstances. In rivers and lakes, pollution, erosion, and sedimentation drastically change species composition. Everything from invertebrate larvae to fish may die off or be replaced by other species more tolerant of the polluted or modified waterways.

Hunting, poaching, and commercial harvesting may be so intense as to extirpate an animal or group of animals from an area or region. The African gray parrot and South American macaws face threats from those supplying the demand for pets. Incidental mortality in fishing nets threatens many of the world’s populations and species of sea turtle. Overharvest of commercially valuable species has created a litany of crashes such as California sardine, North Sea herring, blue whales, kaluga sturgeon, and southern bluefin tuna. As a valuable source of meat and a denizen of potential rangeland and farmland, the pronghorn antelope of the western half of the United States, like the American bison, faced extirpation by the 1900s.

Exotic species, those species accidentally or intentionally transported by humans into new places, often eliminate native animals via predation, competition, or keystone effects on structure and function of the ecosystem. The introduction of mosquitoes into Hawaii brought bird malaria for which the birds were no more prepared for than the peoples of the Americas were for the introduction of smallpox from Europe. An inoculum of larvae in ship ballast introduced zebra mussels from Europe into the Great Lakes of North America. In the early 1990s, the mussel’s spread was spectacular, and with it has come dramatic declines in the abundances of phytoplankton and the fish and invertebrates relying on the phytoplankton. Competition from introduced North American gray squirrels has eliminated the native European red squirrel from much of its former range in England and Wales.

With respect to restoring their wildlife, Australia and Israel provide interesting contrasts. Both have seen their native mammals ravaged. In Israel this has gone on dramatically for millennia whereas it is more recent in Australia. In Israel, overexploitation and habitat modification have been the bane of most animals like lions and crocodiles, both extirpated long ago. Deforestation, reaching its nadir under the Turks just prior to World War I, nearly extirpated the subspecies of European red squirrel and jay from Israel’s wooded habitats. In Australia, wildlife habitat is much more available and overexploitation generally more benign than in the Middle East. However, introduced species (red foxes, feral house cats, and European rabbit) of animals and plants have dictated the decline in numbers and range of comparable Australian mammals. Having contributed to their extirpation on the mainland, cats now occupy Kangaroo Island off of southern Australia and threaten the last remaining population of Tamar

wallaby. Feral goats compete with and threaten the dwindling population of yellow-footed rock wallabies in the Flinder's Range. Red foxes prey heavily upon Australia's native small mammals and consume the eggs of ground-nesting birds.

The reasons for the absence of animal species from their former range are manifold but fall roughly into the categories of habitat change, overexploitation, or exclusion by animal species nonnative to the particular location. Understanding the reason for the absence of an animal or community of animals is the essential starting point for animal restoration.

Site Assessment and Habitat Restoration

All species have the capacity to grow exponentially under ideal conditions, but no population can grow exponentially forever. There are limits to growth, and population interactions such as competition and predation from other species can exclude a species from a community. The goal of site assessment and habitat restoration is to ensure near ideal conditions for the single species or the community of animals under restoration. Ideal conditions means ample food, space, shelter, and safety from predation. Limits to growth invites a consideration of specific factors in the environment that might currently or ultimately limit the growth and size of the animal's population. Considerations of competition and predation focus on which current species at the site, possibly exotic species, might preclude a successful introduction of the desired species to the site.

Site assessment evaluates whether the area offers an appropriate combination of food, safety, shelter, and space for a small population of animals to grow exponentially and prosper. If conditions are not appropriate, then habitat restoration must precede animal restoration. If the vegetation of a site has been heavily degraded, animal restoration may await plant restoration. At Midewin National Grassland south of Chicago, long-term hopes include first restoring the tallgrass prairie and then reintroducing elk and bison. The site is currently a mix of abandoned munitions facilities, farm fields, pastures and assorted oldfields, woodlots, and groves. Wetland restorations often require establishing the aquatic and surrounding vegetation and then passively or actively reintroducing the associated aquatic invertebrates (usually all passive), vertebrates (usually passive but nest boxes or nesting platforms may be used to encourage the return of waterfowl, egrets, or herons), and fish (sometimes passive or active). Different species have different needs, and reconstructing those habitats that fill an animal's needs is central to attracting wildlife or to introducing wildlife.

The possible reasons for the animals' absence from a site focuses site assessment. Often several factors combine to explain an animal's absence. When habitat alteration or fragmentation changes and reduces the diversity of animals, the first step is to determine whether the site has been, or needs to be, revegetated to its former state. This condition of the site does not have to be exact with respect to its former state, but rather it need only include the salient environmental factors that favor the animal's ecological requirements and aptitudes. For instance, many bird species are most responsive to the structure rather than the exact composition of the vegetation. Hence, bird community restoration can commence with

promoting the appropriate vegetation structure rather than being particular to its composition (which may be the goal of a corresponding plant restoration). Habitat fragmentation offers unique challenges because the remaining area may simply be too small to successfully support the desired animal or animal communities. The site assessment may examine the need for more space or wildlife easements, the need for corridors to connect habitat fragments, or the need to enhance the quality of a habitat fragment beyond its natural state to permit the successful persistence of animals in a smaller, more confined space. At Jackson Hole, Wyoming, a wintering elk population is maintained on supplemental hay within a fenced pasture surrounded by the extensive human developments that have robbed the elk of most of their wintering habitat. In spring, the elk return to their natural mountain pastures. In Israel and elsewhere, feeding stations stocked with animal carcasses or offal have been used to facilitate the maintenance and restoration of such animals as wolves, griffon vultures, and eagles.

The California condor provides an illustration of a complex site assessment. Reasons for the decline of condors that culminated in their removal from the wild in the late 1980s included too small a population (demographic threats), habitat fragmentation, lack of carcasses, and lead poisoning from carcasses containing lead shot or bullets. The restoration plan called for captive breeding, gazetting of habitat and habitat corridors, restrictions on development, and for reasons beyond just the condor, the banning of lead shot for hunting. The actual restoration took several approaches to evaluating the complexities of habitat suitability and the ability to introduce a small population of naive animals. First, less rare Andean condors were introduced as a surrogate species. They permitted tests of the reintroduction techniques and indicators of ranging patterns and habitat suitability. The actual reintroductions have used the original site north of Los Angeles but also additional sites, including one near the Grand Canyon. The California release site has more recently had condors but suffers much greater degrees of habitat fragmentation and development. The alternative sites have seen condors less recently, but have the advantage of offering extensive tracts of original and natural habitat.

In response to habitat degradation or fragmentation, habitat restoration may be as simple as adding nest boxes, as in the case of bluebirds at some sites in northeastern Illinois, or as involved as adding proper soil, microbes, and restoring an entire vegetation community, as in the case of toxic waste sites or former mining operations. Ceasing the use of pesticides or release of pollutants may be all that is necessary to restore a habitat. Peregrine falcons in North America have benefited from the ban on DDT. Portions of fish communities and whole invertebrate communities can recover just from preventing sewage and pollution discharges into waterways. The structure of the environment with respect to shrub cover in arid lands, the mixture of ages and types of trees in forests, and the availability of salt licks and waterholes for wildlife all become considerations for particular habitat restorations. Koala in Australia require particular species of eucalyptus trees as food, whereas gravel beds at particular depths provide spawning grounds for trout of the Great Lakes.

When a species absence is the consequence of over-exploitation, success often depends less on the availability of

suitable habitat and more on the cessation of hunting, poisoning (including mortality from hazardous chemicals and pollutants), harvesting, or poaching. Wolves were exterminated throughout the western half of the United States through individual hunting and trapping and by explicit eradication programs. Their reintroductions into Yellowstone National Park, Wyoming, and the White Mountains of Arizona involve presumably moderate to high quality habitat. The success of the programs probably depends most on the cessation of poaching, which at present is a minor problem for Yellowstone and a major threat to the Arizona reintroduction. In 1989, it was discovered that stock assessments of cod within the Canadian North Atlantic were wildly optimistic. The stock had crashed. Subsequent quotas follow from the premise that habitat quality remains high and that reduced harvest will be sufficient to promote recovery. In Southeast Asia, edible swiftlets face decline and extirpation. The birds nest in caves, use saliva for nest building, and face true "nest predation." Humans gather the nests even as the nests may have eggs or nestlings. Even with complete bans on nest harvesting, places like Sarawak, Malaysia, still face intense nest destruction from local people, pirates from countries such as Indonesia, and organized collecting groups. Policing thousands of cave entrances in often remote places throughout the country is impractical. But, until poaching relaxes or ceases, restoration and recovery cannot be achieved. Having reduced poaching of black rhinoceros throughout the 1980s, the Kenyan Wildlife Service has begun the recovery and restoration of current and former populations.

Habitat restoration for overexploited species requires the first step of controlling the harvesting. However, the absence of wildlife from an area may coincide with other changes to the habitat, some which at first may seem subtle. "Nature abhors a vacuum" is a saying recognizing that unused food or opportunities in an environment often become filled by alternative species or by exotics. Habitat restoration may require controlling the abundance of exotic species or those species that compete or prey. Factors contributing to the decline of red squirrels in England include an increase in oaks and a decline in conifers. Both factors assist the exotic gray squirrel in out-competing the red squirrel. Habitat restoration may require both changes in forest composition and active control measures of gray squirrels. The draining of reservoirs, netting, or poisoning of lakes infested with exotic fish such as carp has preceded several fish restorations in North America.

Sources of Animals for Restorations

Small remnant populations, dispersal from other areas, or active reintroductions provide the sources for animal restorations. Ideally, animal restoration should begin while a remnant population still occupies the site. Such a population, while often small, has the advantages of already being established and acclimated to the site. This avoids problems associated with naive animals unfamiliar with the site. In general, once habitat restoration has assured a quality site, resident populations recover faster than immigrants from other areas, which recover faster than reintroduced populations from captive stock. When remnant populations exist, restoration activities can immediately focus on improving vegetation, improving food availability, improving removal of exotics or competitor species,

and/or ceasing harvesting and pollution. Success is measured by the recovery of the species or the expansion of the species into previously unoccupied parts of the site.

When a restoration relies on immigrants, there are the twin concerns of: "Is the site suitable for the establishment of immigrants?" and "Will the immigrants find the site?" When a site such as an oldfield, mine tailings, or forest clearcut is restored, there will usually be successful invasions of insects, soil invertebrates, aquatic invertebrates, mammals, and birds from the environs. For instance, in an oldfield subject to small experimental prairie restorations (Howe and Brown, 1999), there was an invasion of two small mammals (prairie vole and white-footed mouse) and some red-wing blackbirds have shifted their breeding from a nearby pond to the prairie plots. Mourning doves preferentially feed on rather than off of the prairies. Invasions of insects, birds, and mammals ease the restoration effort but sacrifice complete control of the resulting composition of animals. Species that are already well established and abundant in the region of a restoration are the most likely invaders. Rare and remote species are the least likely. Target species may require coaxing in the form of habitat corridors connecting the restoration site with existing populations. Temporary augmentation with food or nesting boxes can encourage reestablishment. In Tsavo West National Park, Kenya, rhinos have been corralled into a sanctuary (ca. 70 km²) that is much smaller than the whole park (ca. 9000 km²). The sanctuary is fenced to keep the rhinos in, patrolled to protect the animals from poaching, and supplied with piped water to maintain permanent water holes.

Animal restoration may require the active reintroduction of animals (Bowles *et al.*, 1994). This is best done by translocating individuals from wild populations, but may require captive breeding. Wild populations provide experienced individuals, whereas captive animals may be particularly naive and unfamiliar with the wild. The reintroduction population should have the appropriate balance of sexes and age classes and sufficient genetic diversity to preclude serious consequences of inbreeding. When the reintroduction is very expensive, is politically sensitive, or is from a very small source population, great care goes into ensuring that the site offers close to ideal conditions and that the animals are prepared for the new environment. When animals are relatively cheap and available, the reintroductions can be more numerous and there is room for experimentation. Wild asses (onagers) in the Negev Desert of Israel, pronghorn antelope in Arizona, lynx in Switzerland, white rhinoceros in Lake Nakuru of Kenya, and peregrine falcons in various midwestern cities all provide examples of reintroductions from captive or wild source populations. In the case of the Guam rail, this bird had been driven extinct on Guam by the introduction of the brown tree snake. Rather than attempting the impossible task of eradicating the snakes on Guam, the rail has been reintroduced on a neighboring, snake-free island.

Promoting Microbial Diversity

Microbial Diversity and Functional Redundancy

Compared to plants and animals, microorganisms are highly diverse and offer a special challenge to understanding

biodiversity and to assuring successful restoration. Microbes should be the underpinnings of any discussion of biodiversity as they constitute the vast majority of the diversity of any ecosystem at any location, yet are rarely even mentioned in terms of maintaining diversity. Microbes should be a focus, not an afterthought, for restoring disturbed lands. Without animals and most species of plants, ecosystems would stabilize and most ecosystem functions would be performed. Without microbes, the ecosystem would cease to function.

Estimates of microbial diversity range up to 10^5 prokaryotic taxa per gram of soil, although 10^4 is generally a more accepted value. In a study of restoration of a Wyoming coal surface mine, 57 different fungal taxa were found out of 135 colonies randomly chosen from approximately 12,500 colony sources (spores, hyphal fragments, bits of organic matter). These taxa were evaluated within a 4-cm² area (using 5 g of soil). Given the numbers, it is not surprising that a large fraction of these organisms remain undescribed. Recent estimates suggest that less than 10% of soil organisms ranging from bacteria to spiders have been described. And, a few efforts that extracted DNA directly from soils have even found new kingdoms of prokaryotes. Despite the difficulty in estimating diversity, every study published has shown a loss in the richness of taxa with severe disturbance. This ranges from soils in the Pumice Plain of Mount St. Helens, which was sterilized, to burned areas in which only the aboveground material and soil surface were directly affected. Because of the extremely high microbial diversity, the concept of microbial functional redundancy has been raised. Among those thousands of species, how many need to be restored to maintain ecosystem functions? This is the single largest challenge for studying soil microbes and restoration.

There are three critical issues for evaluating microbial diversity and restoration. The first issue is defining the spatial and temporal distribution of species and functional groups and their relationship to ecosystem processes. The second concern is assessing the richness of organisms within the different functional groups. The third is the system-level capacity for dispersal and natural reestablishment versus the need for artificial introduction of microbial inoculum.

Spatial and Temporal Arrangement

Just as important as the richness of organisms are the changes in their spatial and temporal distributions. Unfortunately, few studies have evaluated microbial communities using species increment curves or overlap estimates. Several types of analyses are critical to understanding biodiversity and restoration. These include species $\times$ area, species $\times$ time, and dispersion relative to ecosystem processes. Unfortunately, few data sets are available to evaluate microbial recolonization on this basis.

Microbial richness estimates tend to be taken on a per-sample basis. However, plants and animals tend to be analyzed on an area basis. This makes comparative studies difficult but opens an important area of research. Nevertheless, evaluating the spatial array is absolutely critical. Fungi, for example, exist as a network of hyphae (a mycelium) extending from a few millimeters (such as a *Trichoderma* colony

occupying a single fern petiole) to tens of meters in diameter (fairy rings, or the giant Wisconsin *Armillaria*, for example). For the same Wyoming data set, the species increment rate was the same up to the size of a 400-cm² patch of disturbed as well as reference area (Figure 4). However, in the disturbed site, as one expanded outward, the species increment rate declined whereas it continued to increase in the reference area. In the reference area, new species were added as the habitat changed. In the disturbed area, the habitat was rather uniform across the site (in this case, mixed, respread topsoil on a surface mine). Thus, one conclusion is that microbial activity and composition become more diffuse and repetitive across scales in severely disturbed areas, and overall landscape diversity is lower than in native undisturbed areas.

Frequency of sampling over time is also crucial for describing microbial biodiversity. Many microorganisms are only identified based on sporulating structures. However, these organisms may be present continuously but can only be found periodically. For example, macrofungi are spread widely in the mycelial stage and live for many years. Several continuous years of observations are needed for the right conditions to occur before a sporocarp forms. In many cases, fruiting times may occur over successional time. For example, on Mount St. Helens, establishing the first ectomycorrhiza found on the Pumice Plain took 5 years. We never saw a sporocarp to identify the fungus that formed on the ectomycorrhizal root tips of conifers. Development of techniques for DNA fingerprinting will eventually allow us to identify more of these organisms even when they do not sporulate.

Samples are often taken at the wrong time, leading to erroneous conclusions about microbial diversity. For example,

Figure 4 Species increment curve for microfungi at a Wyoming surface mined site. Shown are the taxa in the reference area (squares) versus the disturbed area (diamonds). The increment curve for the reference area is linear through the 375 colonies across the entire area ($y = 1.88 + 0.413x$, $r^2 = 0.997$). The curve for the disturbed area for a small area (4 m²) is not significantly different from the reference area ($y = -6.743 + 0.435x$, $r^2 = 0.998$) but the slope (0.187) is significantly lower ($r^2 = 0.94$) across the larger areas. These results indicate that at small scales, microbial diversity remains very high. However, at the landscape level, microbial diversity is lost in disturbed communities.

soil animals migrate vertically in response to soil moisture conditions. Soil samples are normally taken from surface soils. Thus, the mesofauna may only be detected when they return to the surface. Usually soil organisms are sampled at the convenience of the investigator, but microbial populations are often event driven (e.g., precipitation). Thus, frequent or a deterministic sampling regime is needed to detect their presence.

Spatial relationships are just as crucial as temporal ones. Ecosystem processes (e.g., decomposition, mineralization, and immobilization) are not uniform across an undisturbed area. Microbial-regulated processes tend to be highly patchy and organized to optimize production. However, possibly the greatest impact of disturbance on ecosystem dynamics is spatially mixing soils and creating relatively uniform conditions across a site. In fact, this led to an oldfield view of succession that still largely dominates restoration practices, where a relatively uniform aboveground community is planted. However, succession may be a patchwork of starts and stops, with a few initial colonists acting as islands that become the nuclei for future colonists. Succession and microbial composition and activity are tightly coupled to the developing patchwork. In restored or recovering ecosystems, these patch recovery patterns are evident. In many abandoned, disturbed sites, no spatial recovery is detectable.

Diversity and Functional Groups

The biodiversity of types of microbes in ecosystems is daunting. However, to a certain degree, maintaining or recovering the functional groups of microbes is the first critical task in restoration efforts. Microbes play every ecosystem role at every site. In fact, microbes alone can, and do, form fully functioning ecosystems without higher plants or larger animals. In the most extreme environments of the Sahara desert and the uplands of the Antarctic Dry Valleys, microbes are the only living organisms, existing on aeolian-deposited or ancient carbon inputs. In many extreme environments, microbes make up the entire ecosystem. These range from the simple endolithic (inside rocks) communities of the Dry Valleys of Antarctica to the thermal pools of New Zealand and Yellowstone geysers. As one proceeds to more favorable environments, more and more types of microbes emerge, subdividing the processes of primary production and decomposition. At all sites, microbes undertake primary production (bacteria, cyanobacteria, algae). The relative contribution of the microbes to the overall proportion of net primary production tends to range from high in more extreme environments (such as deserts and tundra) or situations with dispersed nutrients at low concentrations (open oceans) to low in conditions highly favorable such as tropical rain forests.

In addition to directly fixing C, microbes also catalyze the nutrient cycling processes that transfer elements directly to plants or convert unavailable nutrients into forms that can be taken up and utilized. Thus, they are indirectly linked to carbon fixation by providing limiting resources. Although these organisms are generally modeled as “microbial mass,” they often live symbiotically with plants. Mycorrhizal fungi probably have the largest biomass within this group. These fungi

form mutualisms with plants and transfer from soil to plant a range of soil resources, from water to N to P. Importantly, they can also make unavailable soil resources, such as bound P, available, by producing organic acids and phosphatases, and Fe with siderophores. Other prokaryotes fix atmospheric N₂, ranging from free-living forms such as cyanobacteria and *Arthrobacter*, to symbionts such as *Frankia* and *Rhizobium*. Other microbes catalyze almost every other nutrient transformation that is biotically important to the sustainability of ecosystems, from N and S transformations, to Fe state transitions, to immobilization of heavy metals and bioremediation of toxic organics. In the case of mutualistic symbionts, many studies have demonstrated that an increasing diversity of species and genotypes can be critical to establishing and maintaining a diversity of plants.

Microbes are the dominant decomposers. Higher animals only take a small fraction (1–10%) of the NPP; the remainder of the energy goes to microbes. The animals themselves constitute a source of a slightly different C source from plant material, making a new type of C resource. Microbes then utilize almost all of the remaining plant material, thereby releasing the nutrients immobilized in plant tissues. Only a small fraction of C remains, as highly complex plant constituents or recalcitrant microbial compounds. These are critical in that this forms the organic matter essential to recovery of all sites.

Free-living Saprobes

In every study, microbial diversity even of disturbed lands continues to increase with increasing sampling. While the actual slope of species increment curves may be lower than for undisturbed areas, it still remains very high. It is not clear if the reduced diversity of microbes is a factor in these detrimental responses. However, it is clear that if the environmental conditions for free-living microorganisms are present, a high diversity of species and a high density of individual cells will reestablish. Thus, restoration of free-living microbes is largely a matter of management of the soils, rarely by inoculation with bags of “beneficial” microorganisms. To date, there is no evidence that biodiversity per se of free-living microorganisms limits saprobic microbial activity in restored lands.

Free-living saprobes form the bulk of the microbial diversity in both functional pathways and the diversity of taxa. As we look at the known studies, those processes catalyzed by free-living microbes always occur, sometimes in detrimental levels. For example, *Thiobacillus ferrooxidans* uses Fe²⁺ in pyrite, which results in the release of sulfuric acid, detrimentally reducing the pH of streams. Immediately following disturbance, there is a rapid mineralization of N, resulting in N leaching and denitrification. *Reduction* in some of these microbial-catalyzed processes often is an important restoration task.

Soil Animals and Food Webs

Microbes consist of prokaryotes and fungi. These are capable of immobilizing nutrients such as N in the presence of excess C. Soil formation is also dependent on mixing of surface organic matter down through the horizon. These activities are undertaken by a food web of enormous complexity. Soil

Figure 5 Food web channels. Carbon is allocated from plants initially to four critical microbial functional groups. Parasites, especially nematodes, take a large fraction of the net primary production and largely respire it away. This provides little benefit to soil organic matter and should be discouraged, probably largely by weed reduction and initiating a diverse plant mix. Mycorrhizal fungi provide resources in exchange for their carbon and also appear to be critical for producing stable soil organic matter. Soil bacteria and fungi are two separate webs that are grazed by different animals. While the fungi and bacteria mineralize C, they can simultaneously immobilize critical nutrients. The animals are important to retain the nutrient mineralization process as well as mixing in soil organic matter.

animals generally invade rapidly, either dispersing directly or by moving with soils or other materials. Soil food webs are generally characterized using functional groups as the richness of species is simply too high to characterize in detail. Food web analyses indicate that there are distinct channels (Figure 5) that can be affected by the soil conditions and the composition of the microbes. Undertaking detailed studies of the role of biodiversity in these food webs is a critical future task. We currently do not know if species changes really matter to the recovery process.

Symbionts

Symbiotic microorganisms are much less diverse and clearly play critical roles in the establishment and persistence of vascular plants and plant composition. These roles are basically of two types, pathogens that inhibit plant growth, and mutualists that extract resources and exchange those resources with plants for energy or provide protection in some form, again in exchange for energy.

Plant pathogens are of two basic types for our purposes, specialists and generalists. Specialist pathogens are those that are associated with only a single species or group of host species. They tend to be highly diverse. Generalist pathogens tend to be widely spread across plant groups. Specialist pathogens are known to be devastating in agricultural ecosystems. However, they tend to be much less of a problem in restoration efforts. This probably results from the efforts made to restore a diversity of plants, making it more difficult for a pathogen to find a host and build up adequate inoculum densities. Exceptions exist when there is a high prevalence by a single species coupled with an exotic introduction.

Generalist pathogens may be another matter. These are highly diverse organisms that often live as saprobes except when conditions prove favorable to a parasitic lifestyle. For example, there are a wide variety of fusaria and rhizoctonia fungi found in virtually all soils. These can destroy a wide variety of plants under appropriate conditions. *Phytophthora cinnamomi* is responsible for loss of plants ranging such as the eucalyptus in the Jarrah forest in Australia. Often, these are almost undetectable except for very short times. In Wyoming, snow mould reduced sagebrush densities up to 60% and

reduced growth in the survivors. This "mould" was a complex mix of fungi, not *Typhula sp.* found in the snow mould diseases of wheat. The disease was opportunistic and only found during El Niño years of high autumn rains and locations of high snowfall accumulation. It was found only one year and only in locations of high snowfall. Plant parasitic nematodes are always found in soils. They are responsible for high levels grazing, but, remarkably, rarely can nematode damage be observed in a restoration project.

Thus, despite the examples where disease was present, there are remarkably few demonstrations where diseases were highly diverse or markedly changed the outcomes of a restoration effort. Even under rather optimum conditions, such as tropical seasonal forests, we have observed few instances of root or shoot disease and then, it tended to be single root tips or individual leaves, but not widespread across a site. This supports the need to establish a diverse plant community. Clearly, it is generally not desirable to restore pathogens to a restoration site.

Mutualistic symbionts are relatively diverse but that diversity may play unique roles in restoration. Probably the best known are N-fixing prokaryotes. Legumes tend to be important early colonizers as N often limits primary production. In croplands, nodulation tends to be highly specific. This led to the all too common practice of using commercial inoculum. However, at sites ranging from glacial outwash in Alaska to Mount St. Helens to a seasonal tropical forest, we have planted or observed invading legumes. In no case were legumes present and functioning nodules absent. We know little about dispersal of rhizobia, but they do appear to be dispersed readily. Further, we now know that host specificity, at least for *Rhizobium*, appears to be largely associated with plasmids and not a nuclear genomic component. Thus, limitation in nodulation is likely not a function of the presence of rhizobia, but of the conditions of the site.

The effectiveness of the nodulation, however, could be an important question. In well-established hot deserts, *Bradyrhizobium* was an efficient bacterium stimulating high rates of N fixation. However, it was slow-growing and deep in the soil profile. *Rhizobium* was fast-growing and found near the surface. It rapidly colonized plants but was not an effective fixer.

In pasture soils, different rhizobia are distributed in patches scattered across a site. Thus, while the presence of rhizobia is likely not limiting to restoration, having a diversity of populations capable of acting with a range of plants under a range of conditions may be important.

We know far less about *Frankia*, although there is a wide diversity of associated plants. In bioassays of respread cold-desert soils, we found that the plants failed to become nodulated. However, the soils had high N concentrations, which may have restricted activity. Alternatively, invading species such as Russian Olive has nodules even in areas where it has previously not been found. Unfortunately, beyond just a few observations of groups and N fixation rates, there are no studies of the diversity of N-fixing species or genotypes in restored areas of these critical groups.

Mycorrhizal fungi have been studied in much greater detail. Their diversity is highly variable. In desert sites, we have found as few as two or three species. Alternatively, in forests, there can be hundreds of species and thousands of genotypes. These fungi are often eliminated by the disturbance event. However, even when they are not completely eliminated, the diversity of species is often radically altered.

Moreover, many species depend on a mycelial network that can extend up to many meters across. This spatial structure is always broken up, providing opportunities for new taxa to invade. The resulting pattern is an increase in the intraspecific diversity with more, smaller clones. As these clones expand, some die and disappear while others continue expanding into the open habitats. Thus, intraspecific diversity initially increases as many propagules arrive and then declines as fewer colonies come to predominate.

Recovery of symbionts is a critical limiting step in restoration. There are two limiting steps: first, invasion of propagules, and second, establishment on site. Invasion is by physical or biological vectors. The most notable physical vector is wind. Wind has been shown to move organisms as large as mycorrhizal fungal spores up to 2 km. However, there are important limitations. Spores larger than 70–100 μm in diameter are rarely wind-dispersed. In those cases, animals are the vectors for microbes. Many animals feed on microbial spores. This can occur directly. For example, the diet of many rodents can be predominantly fungal sporocarps. This was the major means for mycorrhizal recolonization on Mount St. Helens following the eruption. Other propagules are transported unintentionally. Ungulates and rabbits feed on forbs and grasses, but in doing so, they tear plants from the soil, bringing fungal hyphae and internal spores and vesicles. Animals such as gophers preferentially feed on the nodules of legumes in addition to mycorrhizal fungi. The microbes are adapted to pass through the guts and are deposited across restored sites. Thus, just as for plants and animals, a key factor in restoration is the proximity of the source areas (Figure 6).

Microbial Establishment

Different microbial species have different abilities to reestablish on a disturbed site. Because of their remarkable diversity, we are unable to artificially return even a small fraction of the microbes necessary for successful restoration. Thus, dispersal

from surrounding areas is critical. In all of these invasions, two factors emerge as critical: distance and directionality for the appropriate vectors, and a suitable site. Adjacent source areas are important for reinvasion. At Mount St. Helens, for example, disturbed areas within or adjacent to surviving patches were rapidly recolonized. It took several years for sites at a greater distance to recover (Figure 6). This pattern can be found in many other areas. Both physical and biotic vectors travel along specific pathways. These pathways must be present. In areas without appropriate connections allowing vectors (wind flows or animal immigration), the microbes will not invade.

Just because a microbe reaches a site does not mean it establishes. An appropriate host must be present and the soil conditions must be favorable. This can be facilitated in the planting regimes. For example, planting in patches provides windbreaks, increasing harvest of wind-dispersed microbes in addition to organic matter and other seeds. These patches also are lures to animals that are dispersing microbes. Thus, restoration of the microbes on a site often rests on reconstructing a spatially complex structure that provides protection from wind and for animals.

Another mechanism for restoring microorganisms is simply to respread the original, preferably fresh, topsoil. When topsoil is limiting, it can be stored for a short while and respread. However, mining studies have repeatedly demonstrated that as a mine moves, the newly stripped topsoil can be immediately replaced into the newly restored area. This facilitates microbial recovery

Figure 6 Invasion pathways and source areas. Recovery of microbes on Mount St. Helens can serve as a model of reestablishment. There were three critical types of disturbance. In area A, virtually everything was sterilized. Area B was the blast zone, where everything aboveground was eliminated and ash was deposited up to a meter in depth. Area C was the area of high ashfall. Area C recovered rapidly as most organisms survived in protected areas, establishing on the ash within the first year. This included mycorrhizae, nematodes, nitrogen-fixing bacteria, basidiomycetous fungi, mites, and collembola. Some small patches, where pocket gophers survived and emerged, served as islands. Invasion via animal dispersal also occurred from area C (pathway 1). Recovery across the site was well underway within 2–5 years. Area A was largely invaded from vectors moving from area C (pathway 2). This process was quite slow. Windborne saprophytic fungi (primarily imperfect fungi and bacteria) came in almost immediately. Symbiotic nitrogen-fixing bacteria established in 2 years, from legumes probably dispersed by birds. Other symbiotic microbes took 5–10 years to reestablish.

rapidly. Salvaged transplants would have the same effect of introducing microbes into a disturbed soil.

In circumstances where soil microorganisms are completely lost, it may be necessary to inoculate. We know of no cases where inoculation of bacteria or saprobes has been done directly to facilitate microbial processes, although use of fresh topsoil or salvaged transplants is commonly done. However, mycorrhizal fungal inoculation can improve establishment, particularly of trees and shrubs, in areas where dispersal is limited due to long distances to source areas or where toxic conditions eliminate the native microbes. A few ectomycorrhizal fungi can be cultivated and, in some cases, limited endomycorrhizal inoculum is available through a few companies.

There are no standards for microbes and restoration. Some protocols require the addition of symbiotic mutualists, but all others assume that microbes recover just fine and will “do their jobs.” In fact, soil microbes probably never “stabilize.” Their short individual life spans, coupled with the ability of some members of each functional group to invade and establish, makes assessment of composition and activity difficult. Inoculation can be an important practice in conditions where little or no inoculum for an entire functional group remains and has little chance for reinvasion. However, restoration requires management of soils, plants, and animals to encourage natural migration, patch structure for concentration of resources, and a complex structure that facilitates spatial and temporal diversity in ecosystem processes. If these conditions are met, it is likely that microbes will be capable of taking care of themselves quite well.

Conclusions

Assessing Restoration Success

These examples of restoration of plants, animals, and soil microorganisms all show the difficulties and limitations of restoration of the entire richness of a prior existing community. While dominant plants and animals may be reintroduced, microorganisms are all expected to recolonize naturally. The resultant lower diversity restored communities indicated that if preservation of biodiversity is the goal, then conservation prior to disturbance is the preferred alternative, rather than restoration after disturbance. In focusing on species richness, we have placed little emphasis on ecosystem functioning, even though restoration of functioning is one of the major goals of restoration. Natural ecosystems provide ecosystem services, such as water supply, oxygen, soil stability, natural products, and so forth for free. Reclamation or rehabilitation is usually sufficient to provide these basic services, without the necessity of reintroducing all of the original biodiversity.

Measurements of both structure and functioning are used to assess restoration success. Restoration success is usually assessed by comparing the restoration site to a reference area, a native site with structure and functioning that are predetermined as the restoration goal. Measurements are compared between the reference and restoration sites. Structural measurements, such as the richness, density, and relative

composition of species, are easier to measure than functional measures such as decomposition, nutrient cycling, erosion rate, or biological functions such as species reproduction and mortality or food web energy throughput. Yet it is the functional measurements that we need to determine whether the restored land has really stabilized, not simply the relatively easy measurements that require species counts. Measurements of restoration success are often not legally required, so many restoration/reclamation efforts receive no assessment at all. When they are, a species count, density, or percent cover is often all that is required to declare success.

Designer Ecosystems

Preservation of certain rare species may require manipulation of the ecosystem to stabilize their populations, possibly to the detriment of associated species. Such actions are already taken in numerous situations. For instance, wetland parks for shore birds have been diked, dredged, and dammed to create aquatic habitat for bird species with different water depth requirements. Pastures in Europe receiving high anthropogenic nitrogen deposition are mowed at critical times of the year to reduce the growth of nitrophilous-dominant plants and promote survival of rare plant species. James MacMahon has termed these “designer ecosystems” because they are highly managed ecosystems that have a specific conservation goal, compared to the ecosystem where the species in question may occur naturally. Biodiversity has become highly manipulated in many areas where human populations are dense and where the remnant landscape is managed to promote as high a diversity of species as possible. Virtually all restored communities are missing species, so in one sense restoration may be considered an unintended experiment to determine the impacts of rare or other missing species on community and ecosystem functioning. This will require more research and monitoring than has been done in the past. One aspect of ecological restoration that has not been emphasized in this article is the general lack of data. Many sites are restored that have never received any kind of monitoring or research, or the data are simply not available. The generalization that restoration will not return the original diversity holds for the limited number of sites that have been studied, but as more data become available, we will understand more about how to manipulate ecosystems to maximize diversity.

Glossary

Biodiversity restoration Attempts to remove abiotic, biotic, and human constraints on any and all native plant, animal, and microbial species.

Exotic species A species occurring beyond its natural range or potential natural dispersal range.

Habitat remnant A small area that is relatively undisturbed and represents a much larger historical ecosystem.

Nurse plant A plant that shelters and facilitates the growth of others.

Propagule Reproductive unit (spore, seed, bulb, cyst, egg, bud, larva, etc.) that gives rise to new individuals.

Introduction

The desire to restore biodiversity stems from a long history of declining species richness. In the USA, 1175 native plant and animal species have become threatened or endangered and 371 native plant communities are rare (Grossman *et al.*, 1994). Major, widespread losses of diverse gene pools, species, and communities of organisms have challenged conservationists to reverse the trend, recognizing that today's conditions are greatly altered from those under which native species formed communities and ecosystems. Efforts to sustain and restore diversity are widespread, involving private landowners, governmental agencies, and nonprofit organizations such as The Nature Conservancy in USA.

Restoration practitioners who seek to restore biodiversity need to understand a restoration site's historical and current conditions in order to predict whether it can support and sustain more taxa. This requires determining environmental constraints as well as biological and management constraints. Here, we focus on factors that constrain biodiversity restoration by considering genetic issues, single-species and multispecies efforts, and landscape-scale approaches. The effectiveness of biodiversity restoration efforts relates to the degree of degradation of the site and to the effort expended in restoration and long-term follow-up (Zedler, 1999). Where damages are extensive, as in restoring mine-spoils and landfills, major efforts are required to reinstate water flows, rebuild soil, and reintroduce soil microorganisms, vegetation, and fauna. Where much of the native ecosystem is still intact but propagule sources are limiting, restoration of diverse plants and animals might only require species reintroductions.

Judging when biodiversity has been restored is complicated, because every natural community has some common species and many uncommon and rare species. There are few explanations for these natural patterns or for differential loss of species, as a natural area becomes degraded. Differential restorability is also puzzling. That is, the question why some diverse communities are readily restored and others are not. Plants and animals have many individual traits that make broad generalization difficult. Thus, practical, region-specific

handbooks are needed for restoring biodiversity to sites that differ in degree of degradation and the amount of effort that is feasible.

In a global review of restoration outcomes that were compared to degraded ecosystems (89 projects), Rey Benayas *et al.* (2009) found a 44% increase in biodiversity accompanied by a 25% increase in ecosystem services. However, restoration did not recover all of the biodiversity or all of the combined ecosystem services of those documented for their respective reference ecosystems. It is often the case that efforts to restore species richness produce communities that are less diverse than reference systems. Thus, the first priority for sustaining biodiversity is to prevent the loss of natural habitat, including eradication of invasive species.

The second priority for sustaining biodiversity is to remove the abiotic and biotic constraints on native species populations and communities, working at both local and landscape scales. Such efforts require restorationists to sustain genetic diversity, reintroduce extirpated species, and restore assemblages found in reference ecosystems. In addition, restorationists can make greater use of novel opportunities, such as public rights-of-way or sustainable production areas, to keep native species in their historical landscapes. The restoration of biodiversity at the regional scale will likely need to involve both restoration of historically diverse sites and the use of novel approaches in novel sites. Both efforts benefit from strategic landscape planning and ecosystem-specific guidance for restoring biodiversity.

Genetic Considerations

Populations need genetic variation to respond to environmental stresses and to evolve as the environmental conditions change. Restoration ecology had its beginnings with early research on population genetics when Anthony Bradshaw found that some genotypes of the grass *Agrostis* could tolerate heavy metals while others were unsuitable for revegetating contaminated mine-spoils. Today, ecological restorationists try to select appropriate genotypes for species reintroductions,

choosing propagules from locally adapted populations. In at least one USA case (giant reed, *Phragmites australis*), they also need to be able to distinguish the native strain from the aggressively invasive exotic strain. Restorationists would aim to eradicate the exotic strain, while retaining the native to aid in restoring brackish wetlands. Genetic composition is thus an early concern in deciding how to restore biodiversity.

Issues

Restoration plans can aim to restock depleted populations, reintroduce extirpated species, or, in special cases, introduce new species to a site (e.g., an endangered species that is native to the region but not the site that becomes available for restoration). The gene pool introduced initially can determine the long-term outcome, *via* founder effects. That is, genetic bottlenecks can develop if populations are restored with low numbers of propagules, ramets come from very few genotypes, or transplants are not locally adapted. For example, inbreeding depression is known to impair sperm production and population fitness of the rare Florida panther (Lacy, 1994). But even if populations are locally adapted through the evolution of coadapted gene complexes, outbreeding and the mixing of alleles can decrease fitness. Alternatively, outbreeding depression might be outweighed by hybridization.

Inbreeding, outbreeding, and hybridization are all considered in selecting sources and numbers of propagules. Practitioners consider both within-donor variability and proximity of the donor site to the reintroduction site. Because clonal plants are easily propagated, they are readily used in revegetation efforts. But collecting a few ramets from a single donor clone to produce thousands of plugs will not restore genetic diversity. In Mission Bay, California, restored eelgrass (*Zostera marina*) was genetically less variable than natural eelgrass in nearby San Diego Bay (Williams and Davis, 1996). In contrast, sowing seeds to Indiana's large Kankakee Sands restoration site produced forb populations that were as genetically variable as remnant populations (Dolan *et al.*, 2007).

Genotypic composition and variation have ramifications beyond individual populations, as shown by plantings of three morphologically distinct genotypes of *Spartina alterniflora* (from three USA states) to a salt marsh restoration site in Delaware (Seliskar *et al.*, 2002). Each genotype expressed unique attributes that determine ecosystem structure and functioning, including differential support of animal populations.

Guidance

Existing guidance for restoring genetic diversity is often species specific, due to differences in dispersal, rates of gene flow, and genetic differentiation (Bowles and Whelan, 1994). Guidance for collecting and translocating propagules includes: (1) Donor site variables, for example, the maximum geographic distance from each donor site to the restoration site; the number of donor populations to tap; which donors to tap, considering how collection might deplete the donor population; and the number of individuals to select from each donor population. (2) Restoration site variables, for example, which microsites offer the greatest potential for establishment;

whether to reestablish one large patch or many small; whether to mix genotypes from multiple donors and allow the site to select suitable genotypes. (3) Initial numbers to plant/release; this depends on demography, sex ratio, nonrandom production of offspring, and population fluctuations across generations. A rule of thumb is to establish a population of at least 500 individuals (Lacy, 1994).

Because few species have received adequate study, reintroduction efforts often need research to develop such guidance. In Western Australia, Sinclair and Hobbs (2009) recommended collecting seeds from at least 30 individual shrubs of an outcrossing seeder, *Daviesia divaricata* ssp. *divaricata*, in order to capture its genetic diversity in subsequent plantings.

Captive Breeding and Greenhouse Propagation

Animal populations can be increased through captive breeding before release to the wild, but genetic changes during captivity can compromise survival. For example, captive-bred tamarins that were released in Brazil moved slowly, were confused by scarce food, and unwary of predators, while reconditioned and trained tamarins fared better (Lacy, 1994). Captive populations benefit from continual introduction of wild individuals to help maintain diversity.

Plants that are propagated for multiple generations in warm, humid greenhouses can experience high mortality when transplanted to harsh restoration sites. Hardening (i.e., the gradual shift to harsher conditions) helps acclimate plants that can adjust to outdoor conditions. Like captive breeding, propagation of plants over multiple generations can lead to selection for indoor growth, with loss of traits needed to survive outdoors.

Manipulating Gene Pools

Some authors propose manipulating gene pools to assist evolution and help plants or animals survive extreme conditions. One way is to introduce nonlocal genotypes of the target species. Another approach is to design propagules for extreme restoration sites that are hypersaline, waterlogged, or contaminated. Morphologically varied clones of *Distichlis spicata* were tissue-cultured under various stressors to select for different characteristics, then propagated and transplanted to salt marsh restoration sites. In the field, genotypes differed in canopy structure, belowground production, detritus production, and decomposition rate (Seliskar and Gallagher, 2000). A third suggestion is to create hybrids between local and nonlocal parents (Jones and Monaco, 2009). Manipulated gene pools could enhance survival and overall genetic diversity, although the resulting gene pool would be novel, rather than restored. Several restoration ecologists argue that restoration of novel landscapes requires novel approaches.

Restoring Single Species to Habitat Remnants

The reintroduction of a single species is usually an attempt to reverse its extirpation or restock a native game species, such as

quail in Georgia. Targets also include species that perform valued functions, such as restoring wolf populations to sustain naturally functioning food webs (i.e., control herbivores). Where historical distributions of the target species are uncertain, some plantings or animal releases can be restorations at the regional scale but range expansions at the site scale. Among Southern California's two dozen estuaries and lagoons, only a few still support viable populations of multiple endangered species. Those with continual tidal flushing provide opportunities to establish a grass (*Spartina foliosa*) used for nesting by the federally endangered light-footed clapper rail (*Rallus longirostris levipes*) (Zedler, 2001). Even if neither species occurred there historically, introductions would enhance biodiversity in both the site and region.

Species have been extirpated for various reasons but especially habitat loss. If a species' habitat no longer exists, reintroduction will be limited to the whole-ecosystem restoration projects (see Restoring Communities). If suitable habitat remains, attempts to reintroduce a single species begin with addressing the abiotic and biotic constraints that led to its imperilment.

Abiotic Constraints

Many plant species require specific germination sites, such as open patches with high light penetration. A former habitat that is no longer sufficiently disturbed (e.g., by flood scouring, temporary standing water, treefall/tip-up mounds, mammal burrowing) would lack sufficient open space for plant establishment. Artificial clearings and seed additions can compensate, if seed banks are depleted or dispersal is limiting.

Changes in the frequency, intensity, and timing of fire can reduce rare species populations, and reintroducing fire can be beneficial to ecosystems that burned naturally. Slash pine (*Pinus elliotii*) plantations in Georgia are being restored to long-leaf pine (*Pinus palustris*) forests using controlled burning, which favors an understory wiregrass vegetation and helps sustain the first that facilitates the establishment and persistence of the target tree canopy (Kirkman *et al.*, 2007).

Other abiotic constraints are related to soil conditions. For example, establishment of an annual salt marsh species in California depends on microtopographic conditions, for example, shallow tidal pools that reduce dominance by perennial plants and provide canopy openings (Varty and Zedler, 2008). In USA grasslands, high soil nutrient levels often hinder the restoration of species-rich prairies by helping the invasives outcompete native grasses and forbs.

Biotic Constraints

Habitat loss and competition from nonindigenous species are thought to be the most important causes of the imperilment of rare and endangered species in the US (Wilcove *et al.*, 1998). In California grasslands, exotic annual grasses reduce germination, growth, and survival of native plants, such as the historically dominant perennial grass (*Nasella pulchra*). Efforts to restore target species are also constrained by invasive species, in part because restoration actions typically disturb soils and facilitate seedling establishment.

Some habitat specialists depend on a nurse plant to facilitate germination or establishment. As an example of the latter, many cacti in the Sonoran desert depend on desert ironwood (*Olneya tesota*) to improve the early survival (Suzán *et al.*, 2009). In such cases, restorationists first need to establish populations of the nurse plant.

Parasitic plants need suitable host plants, and the effects of exotics can be quite complex. In San Diego Bay, California, an exotic annual grass (*Parapholis incurva*) of the high-intertidal marsh acted as a pseudohost for a reintroduced population of the endangered hemiparasite (*Cordylanthus maritimus* ssp. *maritimus*). The hemiparasite could attach its haustoria to the grass's roots, but the annual host died before the hemiparasite could mature and set seed (Fellows and Zedler, 2005). In contrast, the natural hosts (perennial plants that provide moisture and nutrients through summer droughts) sustain the parasite through summer, when it produces seed.

Herbivory and predation are further threats. Outbreaks of herbivorous insects can impair reintroductions if vulnerable species are planted too densely. Invasive predators, particularly foxes and cats, challenge reintroduction efforts of many macropod species in Australia (Short *et al.*, 1992). Exotic foxes preyed on a reintroduced marsupial, the quokka (*Setonix brachyurus*), near Perth, Western Australia. And in French Polynesia, the *Partula* snail, a native to Moorea, was driven to extinction after a predatory snail (*Euglandina rosea*) was introduced to control another introduced snail (*Achatina fulica*), which was raised for escargot (Mace *et al.*, 1998).

Animal life histories and trophic levels can help predict potential for reestablishment; for example, late breeders with small clutches are less likely to establish in new surroundings, and carnivores and omnivores are less readily translocated than herbivores (Griffith *et al.*, 1989). Behavioral rigidity is also a predictor; animals that can tolerate human influences flourish in human-dominated landscapes. For example, laboratory-reared and released Mauritius kestrel (*Falco punctatus*) changed their behavior to make use of the agricultural areas and to prey on exotic species, and their numbers increased 10-fold in 25 years (Crade and Jones, 1993).

Management Solutions

Reintroduction efforts are most efficient when the reasons for a species decline or extirpation are known. If unknown, hypothesized causes can be tested experimentally. For example, Pavlic (1996) found that both fire and weed control were needed to reestablish *Amsinckia grandiflora* to northern California grasslands.

Repeated reintroductions are needed when a single trial does not coincide with optimal conditions. In San Diego Bay, sparse pollinators on a small intertidal island limited seed production of *Cordylanthus maritimus* ssp. *maritimus*. After the reintroduction effort was moved to a larger salt marsh where upland patches supported ground-nesting bees, pollination, and seed production improved (Parsons and Zedler, 1997).

Hall (1987, in Primack, 1996) reviewed 15 plant reintroduction projects and provided this advice: (1) Use appropriate planting techniques and match microsite conditions for each species. (2) Select sites carefully; include safe sites.

(3) Document the project in detail. (4) Maintain good growing conditions (eliminate competitors). (5) Monitor over the long term. Griffith *et al.* (1989) reviewed animal re-introduction attempts, focusing on efforts in the United States following passage of the Endangered Species Act. Only 7% of the 93 species of birds and mammals were rare species; most were game species. Resulting guidelines were to: (1) Select quality habitat. (2) Consider life history features. (3) Introduce where competitors are lacking. (4) Use wild-caught animals. (5) Transplant large numbers of individuals.

Restoring Communities

Efforts to restore entire communities often focus on the vegetation, rather than the entire biota (vascular and non-vascular plants, animals, microorganisms) and typically produce assemblages with lower species richness and fewer rare species than that occur in natural communities. As an example, reference forests in southern Mexico supported 30 species of birds, compared to 15 in restored forests (MacGregor-Fors *et al.*, 2010). In a broad survey of restoration outcomes for coastal ecosystems, Borja *et al.* (2010) estimated that full recovery of historical species would require 15–25 years or much longer, even though short-lived species might recover in less than 5 years.

Assembly rules (constraints that a community imposes) are often sought to understand natural successions of species, as well as to guide the sequence of species needed in restoration efforts (Temperton *et al.*, 2004). Tentative rules based on analysis of seminatural grasslands in Germany were to seed annual forbs (generalists) to provide high quality food for herbivores, then add diverse perennial producers and selected herbivores, aiming ultimately to attract additional herbivores and carnivores. A related concept, alternative states, emphasizes that communities shift from their native condition to an altered state, often invaded, once a threshold is exceeded. Both states have internal feedback mechanisms; thus, an invaded state is difficult to restore to the more natural state (Hobbs and Suding, 2009).

Another approach is to plant species judged by experts to have a low coefficient of conservatism ($C \leq 5$), because those with $C = 6$ –10 are less disturbance-tolerant. Use of species with low C recognizes that restoration involves disturbance, and in fact, the floristic quality (an index based on C values) for Midwestern USA prairies is, on average, lower for remnant than the restored prairies (Packard and Mutel, 1997). As a corollary, species with high habitat specificity (e.g., host-specific insects that rely on rare plants) are more difficult to restore. Panzer *et al.* (1995) identified 256 insects from the Chicago area that were dependent on habitat remnants and absent in more disturbed habitats. An exhaustive study of this same region's vegetation showed that more than two-thirds of the native plant species were remnant-dependent and only one-third had broad distributions. Thus, a minority of species occupied a majority of the landscape.

Restoration sites that are near or adjacent to the remnant ecosystems offer the greatest potential for achieving high diversity. The natural dispersal of epibenthic invertebrates from adjacent salt marshes into restored wetlands rapidly restored

diverse assemblages along the North Carolina coast (Sacco *et al.*, 1994) and in San Diego Bay (Scatolini and Zedler, 1996). In both cases, tidal water aided larval dispersal. Still, densities were lower than in reference sites. In the same San Diego Bay wetland, fish species composition matched that of reference sites and densities were higher, apparently because the constructed channels were deeper and broader than natural channels (Williams and Zedler, 1999).

Combining multiple restoration actions with long-term management improves chances of restoring diversity. In Wisconsin, hillside prairies are restored by cutting trees, but burning is necessary thereafter to sustain diverse native grasses and forbs. In New Jersey pine forests, where military exercises eliminated the woody vegetation of dwarf forests (native pygmy pine, *Pinus rigida*), species richness was restored within 2 years using both plantings and mulch (compost to augment soil organic matter and retain moisture; Fimbel and Kuser, 1993). And in Florida, wetlands were restored in phosphate-mining sites within an agricultural landscape by contouring depressions, importing stockpiled sediments, and mulching with substrate from nearby wetlands. These multiple efforts provided dipteran species similar to those in natural wetlands, and the 20 most common species also had similar densities (Streever *et al.*, 1996).

Attempts to restore diverse vegetation rely on species-rich seed mixtures and plantings of seedlings. Animals, however, are usually expected to disperse unaided into restoration sites. Likewise, algal and microbial components are either ignored or limited to the introduction of mycorrhizal fungi where nutrients are a constraint. Reliance on natural dispersal takes longer and favors species with high mobility. Among the most mobile species will be invasive exotics, and those that establish early will hinder restoration of native biodiversity. Plantings are strongly recommended. The constraints on restoring multiple species include abiotic and biotic factors, as for single-species reintroductions.

Abiotic Constraints

The substrate of restoration sites is often inadequate for supporting diverse native plants. In many sites, high nutrient levels reduce plant diversity. In Northumberland, UK, seeding experiments to establish species-rich grasslands showed that fertilizers decreased diversity while grazing increased diversity (Chapman and Younger, 1995). In Saskatchewan, Canada, experiments to control the exotic grasses *Agropyron cristatum* and *Bromus inermis* demonstrated that high nutrient levels, especially nitrogen, favored the weeds and impaired restoration (Wilson and Gerry, 1995).

Insufficient nutrients can also constrain restoration. In the Appalachians, open-pit coal mine reclamation sites are low in nitrogen and phosphorus, because the iron-rich mineral soils weather, oxidize, and form complexes that remove phosphorus (via precipitation) from solution (Daniels and Zipper, 1995). In San Diego Bay, dredge spoils limited salt marsh restoration because the sandy substrate had low nitrogen-holding capacity. *Spartina foliosa* required continual additions of nitrogen to produce tall canopies, which were needed to attract light-footed clapper rails (*Rallus longirostris levipes*) to

nest (Zedler, 2001). Soil that is low in phosphorus can also limit plant growth, especially in uplands. There, mycorrhizae can be added to help plants procure nutrients and moisture.

Unfavorable pH levels develop when fen and sulfate-rich soils are exposed to oxygen. In The Netherlands, acidic soils caused the loss of calciphilic species, and liming did not raise pH sufficiently for native species to reestablish, even after 5 years of treatment (van Duren *et al.*, 1998). Also in The Netherlands, atmospheric nitrogen deposition was found to deplete native species and degrade acidic heath. Further restoration efforts involved liming (to raise pH) followed by sod removal (exposing low-nutrient mineral soil); native plant species were then able to reestablish (De Graaf *et al.*, 1998).

Substrate texture can also limit the restoration of animals. Field experiments showed that ground-nesting Caspian terns (*Sterna caspia*) preferred sand to compacted sediments, so a large nesting site near Lake Ontario was constructed with sandy substrate, which attracted the target birds (Quinn and Sirdevan, 1998). Even the specific texture of sand can determine which species of rare tiger beetles (*Cicindela* spp.) can be restored. Both aquatic and terrestrial burrowing animals have strong preferences for substrate texture.

Insufficient topographic heterogeneity limits the variety of microsites necessary for diverse communities (Vivian-Smith, 1997). In salt marshes, tidal creeks provide conduits for fish and invertebrates to access shallow pools on the marsh plain, and pools develop into feeding oases. In restoring desert wasteland, the excavation of depressions and mounding the spoils to funnel water allowed water, organic matter, and nutrients to collect (Boeken and Shachak, 1994). Such depressions support more plant species.

At the landscape scale, loss and fragmentation of habitats have reduced connectivity among the remaining patches. Both dispersal and recruitment limited species abundances in experimental additions of up to 54 species to 2×2 m grassland plots; species richness increased 83% following one-time sowing of seeds (Tilman, 1997). Processes that overcome natural dispersal barriers can allow novel species to invade habitats and consequently cause marked changes in community composition, diversity, and functioning.

Biotic Constraints

Propagules are often limiting to restoration efforts. Efforts to restore prairie pothole wetlands in North America by eliminating drainage structures (tiles, ditches) were constrained by insufficient seed banks and limited dispersal. After 3 years, restored wetlands averaged 27 species compared to 46 in reference wetlands (Galatowitsch and van der Valk, 1996). On the other hand, propagules of nonindigenous species are often abundant in restoration sites, especially small sites with a high proportion of edge (e.g., many prairie and savanna restoration sites).

In mesic to dry ecosystems, insufficient mycorrhizae can slow restoration by reducing nutrient uptake by target plants. Adding one fungal inoculum might not suffice, since a diversity of mycorrhizal species led greater vascular plant species richness in USA prairies, European grasslands, and Canadian old-field restoration (van der Heijden *et al.*, 1998).

Exotic invaders are especially problematic in restoration sites. Invasions prompt restoration efforts, and restoration efforts often create conditions that favor weedy species. In a semidesert area of Arizona, attempts to establish native grasses in mesquite (*Prosopis juliflora* var. *velutina*) woodland were impaired by the dominance of the understory by an exotic grass, *Eragrostis lehmannian*. Reintroduced natives were sparse relative to the exotic plant, depending on the interaction of several factors, such as fire (a treatment variable) and rain intensity (introductions were done in three successive years) (Biedenbender and Roundy, 1996).

Plant invasions are especially problematic in wetlands. Perennial clonal forbs (e.g., purple loosestrife, *Lythrum salicaria*) and grasses (e.g., *Phragmites australis*, *Phalaris arundinacea*) invade and dominate many types of wetlands. In microcosms with varying levels of water, nutrients, and leaf litter cover, *Bidens cernua*, a native annual, dominated all 24 treatments in the first year. After 5 years, most of the microcosms were becoming dominated by purple loosestrife, with only a few of the original species remaining. Flooding regimes and soil fertility were the main factors influencing establishment and growth of *Lythrum*, with high water and low fertility limiting its dominance (Weiher *et al.*, 1996).

Exotic animals that constrain restoration in San Diego Bay wetlands include sessile invertebrates (e.g., mussels, *Musculista senhousii*) that usurp space on various substrates and fish (e.g., the carnivorous goby, *Acanthogobius flavimanus*) that prey on native fishes (Williams *et al.*, 1998). In some cases, creating a novel ecosystem in a region (e.g., ponds with permanent water in Oregon) provides habitat for exotic predators (e.g., bullfrogs, *Lithobates catesbeiana*), which prey on native species. In other cases, the presence of one exotic species facilitates the arrival of others, resulting in biodiversity loss, not gain. Simberloff (1999) calls this process an invasional meltdown.

Management Solutions

Where restoration begins by removing invasive plants, the characteristics of the invader dictate site preparation; for example, in Midwestern USA grasslands, *Bromus inermis* monotypes are plowed before native species are planted, but *Phalaris arundinacea* needs repeated herbiciding to kill belowground dormant buds. Restoration often needs to be delayed until herbicides are no longer needed. Fire is commonly reintroduced to combat exotic woody plants. Where habitats are small (e.g., remnant prairies along railroad rights-of-way) or where controlled burns are a hazard to people or structures, the inability to reintroduce fire constrains biodiversity restoration.

The more harsh the conditions, the more effort is needed to establish vegetation. Planting seedlings in clusters can facilitate the accumulation of organic matter, soil water, and mycorrhizae (MacMahon, 1998). Planting seeds in safe sites aids germination and revegetation, especially in severe environments. In alpine meadows, disturbed areas around ski runs are ameliorated by covering seeds with fibrous mats (Urbanska, 1995). Mulch is effective where it does not blow or wash away. Industrial byproducts can be used as organic soil amendments, potentially improving soil water-holding

capacity. In San Diego, kelp byproducts are composted with perlite to provide a soil conditioner that accelerated restoration of salt marsh vegetation (O'Brien and Zedler, 2006). Temporary irrigation systems are also used to water seeds and plugs, often for multiple years, until deep roots form and sustain drought-tolerant plants.

Some species need to be reestablished during brief opportunities, such as seasonal rainfall, or following unusual events, such as forest fires, flooding, or winds that uproot trees and expose soil (Primack, 1996). Following bauxite mining in southern Australia, the ripping and cultivation of substrate and sowing needs to be timed to coincide with seasonal rainfall to improve restoration of *Eucalyptus marginata* forests. In Southern California, restoring tidal influence to salt marshes in December or January allows high tides to disperse seeds to newly excavated areas and winter rainfall to assist seedling establishment. The sequence of planting can also be important (Eriksson and Eriksson, 1998). Introducing nurse plants aided restoration of limestone grasslands of northern Switzerland; *Arabis hirsuta* and *Primula veris* established best in the shelter of neighboring plants; elsewhere, seedlings succumbed to drought and substrate-heaving (Ryser, 1993). In a Mexican forest restoration project, the addition of a legume as a nurse plant benefited the restoration of birds by providing a food source (MacGregor-Fors et al., 2010).

Restoring Biologically Diverse Landscapes

Occasionally, the restoration of diversity to large landscapes is undertaken with strategic planning that matches species needs to opportunities, including willing landowners and funding for public improvements. The Southern California Coastal Wetland Recovery Project (www.scwrp.org) is an example. This regional effort involves state agency personnel who aim to reverse habitat loss, remove threats to endangered species, and mitigate impacts of highway, ports, and other developments. Extensive involvement of stakeholders and years of planning have led to several projects that have restored tidal flows to nontidal and semitidal lagoons.

Several watershed planning efforts are also underway, especially within the context of wetland mitigation. Efforts in Wisconsin, Tennessee, and Georgia combine wetland restoration (the focus of the Environmental Law Institute) with biodiversity restoration (the focus of The Nature Conservancy). These nongovernmental organizations are working with multiple stakeholders to develop watershed plans to serve as national models for prioritizing wetland restoration sites and targets to improve water quality, reduce flooding, and sustain diversity within watersheds and downstream waters.

Landscape Objectives

At the landscape (or watershed) scale (several square kilometers), the restoration of biodiversity often has multiple functional goals of value to people (ecosystem services). Such services include managing water quality, treating waste, providing social and cultural functions (visual quality, education, heritage), and offering products (e.g., producing fiber or

food). Multifunctionality is facilitated by spatial and temporal heterogeneity of the restored landscape, with feedbacks from biodiversity. Spatial heterogeneity fosters fluxes between habitats, builds ecological "networks," and fosters species interactions (e.g., a facilitator of a desired species or a predator that feeds on a pest species). Collectively, heterogeneity enhances a landscape's chances of supporting and sustaining biodiversity. To these three landscape-restoration objectives, we add adaptive restoration or "learning while restoring." For all four objectives, long-term study and monitoring are needed to understand and quantify outcomes and thus improve biodiversity restoration.

The ability of a landscape to support increased biodiversity is greater if it includes many large, appropriately located restoration sites. Similarly, restoring biodiversity at a specific site is facilitated where the surrounding landscape has many large natural habitats that still support the target community. Along Delaware Bay, 5040 hectares of tidal wetlands were restored, enhanced, and preserved to mitigate impacts to fish by cooling water discharged by a major power company (Weinstein et al., 2001). Selfrestoration was facilitated by breaching dikes around marsh hay fields and herbiciding invasive *Phragmites* in degraded brackish marshes. Tidal water could then transport propagules of microorganisms, algae, plants, and animals from the adjacent 32,000 ha of fully tidal wetlands, allowing the native grass, *Spartina alterniflora*, and diverse aquatic animals to reestablish. Proximity to reference sites and tidal dispersal were keys to selfrestoration.

Novel Opportunities

Most watersheds are humanized and unsuitable for large-scale restoration. Still, it is possible to restore and retain many of the species that were historically widespread, although not necessarily exactly where they once occurred. Novel sites could be suitable places to introduce native plants that once occurred within the region. Using novel sites for native vegetation would not necessarily restore native assemblages, but it would help sustain some gene pools, augment some populations, and reduce the area of nonnative vegetation, potentially reducing exotic species invasions.

Many European farmers have been given incentives to plant wildflowers to restore biodiversity to arable lands. In Switzerland, landscapes with multiple wildflower strips supported greater diversity of butterflies (and more specialist species) where the area of strips was greater and plant species were more diverse (Aviron et al., 2010). Near Decorah, Iowa, remnant prairie vegetation between a highway and a railroad track was expanded by plantings. In Wisconsin, many private landowners use native plants for landscaping, and children of several dozen schools have restored prairies that teachers use in nature instruction. Presumably, these regions benefit from the cumulative effects of many small sources of propagules.

Plantations differ from natural forests in being monocultures, but they can be managed to provide a diversity of understory plants. In fir (*Abies*) and pine (*Pinus*) forests in western México, seeding of lupine (*Lupinus elegans*) in reforestation sites created conditions that favored the establishment of native forbs and shrubs, considerably increasing

forest species richness (MacGregor-Fors *et al.*, 2010). In New Zealand, indigenous plants and animals occurred in forest plantations that were close to natural habitat (Norton, 1998). In northern Australia, plantations of native *Flindersia brayleyana* and *Araucaria cunninghamii* supported more diverse understory vegetation than did the exotic *Pinus caribea* (Keenan *et al.*, 1997). Planting diverse trees (six conifers and four hardwoods) in Minnesota reduced infection of fungi (*Armillaria* spp.) and increased wood production (Gerlach *et al.*, 1998).

Power line rights-of-way provide novel opportunities to establish habitat for wildlife. Such rights-of-way are typically cleared of trees and shrubs by cutting and use of herbicide, which reduces native plant and wildlife diversity and creates corridors for species invasions. Brown (1995) suggested using competitive cover crops to inhibit the establishment of trees. *Dactylis glomerata* (a nonindigenous grass) reduced survival of two tree species (*Fraxinus pennsylvanica* and *Acer saccharum*), but biomass and diversity of forbs were also reduced. Field experimentation could identify additional suitable native species.

Stormwater management ponds could support greater biodiversity if topographic heterogeneity were increased and shorelines were more convoluted. In Wisconsin, such ponds attract many invasive aquatic species (Johnson *et al.*, 2008). Thus, shoreline plants and aquatic animals need to be planted. Stormwater conveyances can employ native willows (*Salix* spp.) to stabilize banks and floodplains in preference to concrete flumes. Frequently disturbed sites could reduce physical and chemical maintenance and attract wildlife.

Biofuel production also involves frequent disturbance, for example, annual harvesting of grass crops. Biodiversity would be enhanced if native species and locally adapted genotypes were used, if biofuels were grown using diversity-friendly agricultural practices (e.g., avoiding mowing during bird-nesting times), and if the ecological footprint were minimized (low land area per biomass) (Groom *et al.*, 2008). Frequent mowing and removal of all aboveground biomass would likely select for a few grass species and limited animal diversity. Landscape-scale guidelines are needed to phase plantings and harvests and to combine herbaceous and woody biofuel crops to support more biodiversity than in widespread monocultures.

There are concerns that the species that are most adaptable to novel restoration sites will dominate landscapes and restoration efforts will result in “generic communities” (Zedler, 1999). Because habitat restoration involves disturbances, such as contouring and grading, the species that thrive in restored habitats are likely to be adaptable, disturbance-tolerant generalists. While such species have utility in establishing cover quickly and in resisting invasion by less desirable species, biodiversity will not be restored without further efforts to introduce and attract the full spectrum of native plants and animals. Continual experimentation (e.g., seed additions to grassland, as in Tilman, 1997) can serve this purpose while learning more about the abiotic and biotic constraints that limit restoration of various species and assemblages.

Large restoration sites are amenable to experimentation. Most of the constraints on biodiversity restoration can be tested experimentally, for example, varying genetic donors and

translocation procedures, varying microsites for single-species reintroductions, and varying assemblages and sequential introductions in multispecies approaches. Restoration sites are underused by ecologists, but, when approached within an adaptive framework, they afford many opportunities to “learn while restoring.” Adaptive restoration begins by identifying the unknowns that need to be known to restore landscapes or sites. It proceeds in phases, with sequential field experiments that answer the most urgent questions first. Researchers or managers monitor outcomes and then use the results to select and implement the most promising approaches across larger areas. At Tijuana Estuary, California, the first experiment determined that five of eight native halophytes needed to be transplanted as seedlings (the other three could self-restore, given a seed source). A subsequent, larger experiment used that guidance and also determined that amending the soil, planting in tight clusters, and adding tidal creek networks could increase plant growth and overall ecosystem functioning. Adaptive restoration led to a handbook on how to restore the region’s tidal wetlands (Zedler, 2001).

Glossary

Biome Can be defined as a “major regional community of plants and animals with similar life forms and environmental conditions. It is the largest geographic biotic unit, and is named after the dominant type of life form, such as tropical rain forest, grassland, or coral reef.” A single biome can be widely scattered about the planet.

Biogeographic realms Describe the largest division of the historic and evolutionary patterns of terrestrial plants and animals. In these regions, plants and animals evolved in the isolation created by barriers such as oceans, mountain

ranges, or deserts. A realm can be a single continent or cut across continents.

Ecoregions Distinct ecological units nested within biomes and realms. They are defined as relatively large units of land or water containing a distinct assemblage of natural communities sharing a large majority of species, dynamics, and environmental conditions. Ecoregions represent the original distribution of distinct assemblages of species and communities. Ecoregions tend to have flora and fauna quite different from others. They are the smallest ecological unit analyzed in most protected area studies.

Overview: How Protected Areas Are Defined, Selected, and Created

Definitions

Iconic examples of protected areas, recognized worldwide, include the Grand Canyon National Park, the Serengeti National Park, and the Great Barrier Reef Marine Park. These vast natural areas are set aside primarily for nature conservation. In reality, the term ‘protected area’ encompasses a far broader array of places, from tiny, locally managed fishing reserves to large landscapes where people and nature live in a tight balance.

The most widely accepted formal definition of a protected area was developed by the International Union for Conservation of Nature (IUCN) in 2008:

A clearly defined geographical space, recognised, dedicated and managed, through legal or other effective means, to achieve the long-term conservation of nature with associated ecosystem services and cultural values. (Dudley, 2008)

This brief definition encompasses four critical facets:

- **Spatial:** Protected areas are tracts of land or sea with defined and fixed boundaries.
- **Set aside:** The terms ‘recognized, dedicated, and managed’ all point to the need for the site to be treated differently from surrounding areas. Protected areas are often established as legal entities, but this is not required. However, there must be some means of ensuring that these spaces are cared for in a distinct and effective manner.
- **Long term:** Protected areas are seen as long-term or permanent management interventions.
- **Nature:** Cultural values and human use can be central elements of protected areas, but the primary purpose must be nature conservation. Other spatial management regimes for the management of natural resources for forestry,

fisheries, agriculture, or other uses, which do not give prominence to nature conservation, are often not regarded as protected areas.

In application, the term ‘nature’ has been broadly interpreted to include landscapes and seascapes where human activities have considerably altered the original state, but where natural values are still considered as conservation targets.

The IUCN protected area management categories classify, but do not rank, sites based on their intended management approaches (Dudley, 2008).

Ia. Strict nature reserves are strictly protected areas set aside to protect biodiversity and also possibly geological/geomorphological features, where human visitation, use, and impacts are strictly controlled and limited to ensure protection of the conservation values. Such protected areas can serve as indispensable reference areas for scientific research and monitoring.

Ib. Wilderness areas are usually large unmodified or slightly modified areas, retaining their natural character and influence, without permanent or significant human habitation, which are protected and managed so as to preserve their natural condition.

II. National parks are large natural or near-natural areas set aside to protect large-scale ecological processes, along with the complement of species and ecosystems characteristic of the area, which also provide a foundation for environmentally and culturally compatible spiritual, scientific, educational, recreational, and visitor opportunities.

III. National monuments are set aside to protect a specific natural monument, which can be a landform, sea mount, submarine cavern, geological feature such as a cave, or even a living feature such as an ancient grove. They are generally quite small protected areas and often have high visitor value.

IV. Habitat/species management areas aim to protect particular species or habitats, and management reflects this priority. Many management areas will need regular, active

interventions to address the requirements of particular species or to maintain habitats, but this is not a requirement of the category.

V. Protected landscapes/seascapes comprise areas where the interaction of people and nature over time has produced an area of distinct character with significant ecological, biological, cultural, and scenic value, and where safeguarding the integrity of this interaction is vital to protecting and sustaining the area and its associated nature conservation and other values.

VI. Protected areas with sustainable use of natural resources conserve ecosystems and habitats, together with associated cultural values and traditional natural resource management systems. They are generally large, with most of the area in a natural condition, where a proportion is under sustainable natural resource management and where low-level non-industrial use of natural resources compatible with nature conservation is seen as one of the main aims of the area.

Many protected areas do not fit neatly into these definitions. In the United States, for instance, the term 'national monument' refers as much to the manner of creation as to the characteristics of the site. National monuments are created by presidential proclamation, a far simpler process than the creation of national parks or wilderness areas, which require Congressional approval (Hardy, 1998). The Arctic National Wildlife Refuge, classified as IUCN Category IV – Habitat and Species Management – actually functions as a strict nature reserve or a wilderness area because of its remoteness and vast size. At the same time, when Congress approved the creation of this refuge, it expressly allowed the future use of 1.5 million acres for oil and gas extraction. The divergence between assigned category and use varies from one country to another. In many countries, national parks are large tracts of near-wilderness where nature runs its course with little intervention. The legal status of such areas may closely match IUCN Category II but *de facto*, the park, or some parts of it, may resemble strict nature reserves or wilderness (IUCN Category I). By contrast, many of the national parks in Europe are managed landscapes where grazing and agriculture are considered part of a system with considerable biodiversity value and ongoing human activity is integral to the management. Many of these sites are classified as IUCN Category V.

Buffer zones surrounding protected areas are intended to guard against encroachment and mitigate edge effects. Though rarely protected, they may be managed via restrictions similar to those of IUCN Category VI protected areas.

History

Throughout human history, people have set aside land considered to have special natural values. Some ancient sacred sites were protected because of their natural features. Other forms of protection likely arose, planned or otherwise, to prevent overharvesting by restricting access to certain areas for hunting or fishing.

The first historical records of protected areas come from India. Recommendations for protection are made in the Arthashastra texts written in the fourth century BC, and the Emperor Ashoka, in 252 BC, issued the first legal decree for

the protection of wildlife and forests (Bhatt *et al.*, 2008). One of the oldest sites with a continuous record of conservation management may be the New Forest in southern England. This site, now a national park, was set aside in 1079 as a royal hunting reserve, first to protect against local harvesting to maintain a rich stock of game and subsequently for timber. Other early utilitarian purposes for conservation included watershed protection, such as the Main Ridge Reserve declared in Tobago in 1761, and the widespread use of closed or taboo (*tapu*) areas to manage fisheries in many Pacific Islands.

The Yosemite Grant by the U.S. government to the State of California in 1864, to protect its scenic, esthetic, and recreational values against commercial development, typifies the shift to a more modern concept. The declaration of the first national park soon followed with the establishment of Yellowstone National Park in 1872, which by law was "reserved and withdrawn from settlement, occupancy or sale ... and dedicated and set apart as a public park or pleasuring-ground for the benefit and enjoyment of the people" (Yellowstone National Park Act, 1872). Other countries followed the lead: Australia's Royal National Park was established in 1879, New Zealand's Tongariro National Park in 1894, Sweden's Laponia in 1909, and the famed South Africa's Kruger National Park in 1925 (Chape *et al.*, 2008).

International listing of protected areas began in the early 1960s at the instigation of the United Nations; the first list of 'national parks' included approximately 1000 sites. By 2003 the figure was considerably more than 100,000 sites (Chape *et al.*, 2003). In the marine environment, progress was slower. In 2003, only 0.45% of the oceans were designated as marine protected areas; this figure almost trebled to 1.31% by 2010.

Selection of Protected Areas: Reasons

Justifications for the establishment of protected areas have evolved over time. Preservation of wildlife as a food source later became the interest of sports hunters, and still later, for its own sake or for the maintenance of ecosystem integrity. Similarly, the protection of timber stands for lumber has come to encompass the maintenance of forest ecosystem function. Water resources for agriculture and other human uses also came to be valued for the maintenance of biodiversity. Recreation became, and still is, an important motivation. The nineteenth-century romanticism that thought that protected areas were to remain largely free of human presence gave way to the twentieth-century concept of 'multiple use' and the inclusion of human residence within protected area boundaries.

Concern for disappearing species arose in the nineteenth century and informed the protected area theory of the twentieth century. The preservation of small numbers of animal and plant species in zoos and botanical gardens led to the realization that true survival of species necessitated the conservation of the habitat of those species. Increasing emphasis on nature conservation came from growing awareness that sites and species were increasingly at risk of despoliation or extinction. The first tracts of Wicken Fen, England's oldest nature reserve, were purchased in 1899 to safeguard one of the last remnants of a once-vast wetland that was about to be lost. Today the protection of species and habitats lies at the heart of

many protected area designations, and the desire to build more secure systems of protection has led to objective scientific approaches for selecting individual sites and networks of protection.

Esthetic values continue to play a role, in part because scenic areas are valued as a component of recreation. Utilitarian needs and arguments are undergoing resurgence, with growing desire to use natural systems to secure benefits such as freshwater supplies, coastal protection, and carbon storage and sequestration (Dudley *et al.*, 2010; Mcneely and Mainka, 2009).

Selection of Protected Areas: Methods

Generally

Ecological knowledge is a critical input variable for the design of individual sites and of networks. Understanding species' range sizes, minimum viable population sizes, interactions, behaviors such as dispersal and migration, and biogeochemical processes is critical in determining a size and design for a protected area to allow a healthy population to survive. Long-term observations are needed to understand natural variation over time, and both expected ecological succession and disturbance and the potential influence of climate change must be considered.

The edge effects of reserves that adjoin altered land have been well documented. Highly fragmented habitats such as forests with high margin–area ratios will typically have a more altered and less stable population of forest-restricted species than will single tracts of equivalent area. Together with location, edge effects will also facilitate human access, with fragmented or small patches allowing more opportunities for hunting or other anthropogenic disturbance (Gascon *et al.*, 2000). *Ex situ* threats such as water or air pollution, or the spread of invasive species, are difficult to avoid but larger, unfragmented sites may be less susceptible. Location may be critical in avoiding or minimizing the impact of threats from without. In many freshwater and marine habitats, for instance, upstream influences can greatly reduce the value of small protected areas. Considering upstream threats when selecting sites can make a considerable difference.

In the face of pressing conservation needs and the rapid conversion of natural habitat for human activity, conservation organizations and governments have engaged in numerous prioritization exercises, such as the Nature Conservancy's Conservation by Design (Anon, 2006). Prioritization exercises tend to focus on representation of all habitat types. There is also a degree of flexibility that allows for the acquisition of lower priority sites that will be lost if not acquired immediately.

Protected areas are rarely selected or designed based solely on ecological principles. Governments and private organizations rarely have a totally free hand. Political boundaries and private ownership often limit the acquisition of areas with conservation value. Other constraints include economic limitations and the real or perceived impact on stakeholder communities that may stand to gain or lose from site designation and that can be great supporters or vociferous challengers (Borrini-Feyerabend *et al.*, 2004).

Networks and Connectivity

A desire to achieve more secure conservation outcomes has spurred efforts to build comprehensive and systematic approaches to designation. Ecological processes are the true goal of these systems: capturing spatial patterns of connectivity such as migration and dispersion across land and seascapes, ensuring sufficient population sizes and genetic diversity, and securing against loss due to natural stochastic events or anthropogenic influences by replicating protection in multiple locations. These approaches seek to ensure that a full array of diversity is protected in a 'system' of protected areas.

With this in mind, considerable effort has gone into building connectivity between protected areas. Methods can include the consideration of natural dispersion routes and setting of maximum distances among sites to maximize the likelihood of successful movement among sites. Corridors to facilitate movement among sites may be continuous areas of appropriate habitat or may be discontinuous stretches where 'stepping stone' patches facilitate species movements. In the case of migratory species, the concept of connectivity can be very large scale and can traverse multiple countries and even hemispheres.

Systematic planning efforts trace back to plans for a network of *Zapovedniks* (strict nature reserves) to represent all of Russia's natural diversity in 1917 (Danilina, 2008). At global scales the desire to assess progress and encourage addition of new protected areas to global systems led to the development and use of new biogeographic classification systems (Spalding *et al.*, 2007; Udvardy, 1975) to assess global and regional protected areas coverage. Simple overlays of protected areas with such maps draw attention to deficiencies and often drive new conservation effort. More focused conservation effort, based on species richness, rarity, endemism, and restricted range, attempts to identify key areas for special attention.

International prioritization and coordination efforts are largely for guidance, although both the *Ramsar Convention on Wetlands* (Ramsar) and the Convention on Biological Diversity (CBD) carry at least some obligations by signatories to develop minimum coverage and to utilize standard measures of importance and of representativeness. The CBD set targets for protection coverage by member states; the Ramsar contracting parties encouraged a unified approach by adopting the Marine Ecosystems of the World classification (Spalding *et al.*, 2007) to encourage global representative systems (COP10, Resolution X.20, Changwon, Republic of Korea).

At national and regional scales, there is increasingly a legal requirement to develop at least a partially systematic protection of nature. The European Union Habitats and Birds Directives, for instance, by law require member states to protect a large network of Special Areas for Conservation and Special Protection Areas. Known as the Natura 2000 network, which as of 2011 includes approximately 18% of the land area of the 27 European Union nations, these sites encompass key habitats and species that were identified through a systematic review. Many sites were already protected, but the process served to identify gaps, whereas the multinational recognition provided under European law added another layer of legal protection, making it harder for landowners or national governments to remove or limit protected status.

There is also a need to embed sites within a broader landscape management context, to reduce conflicts and build synergies with uses and activities in adjacent land and seascapes. Systematic planning tools exist that enable users to visualize social, economic, and biodiversity information together, to build hypothetical protected area systems, and even, with sufficient input variables, to design systems of protected areas that would accommodate all societal needs and maximize human and natural benefits.

Species Protection

The objective of the CBD is to significantly reduce the rate of biodiversity loss. An analysis of the latest IUCN Red List (IUCN, 2011) shows that the number of species classified as threatened is growing, suggesting that this CBD goal is not being met. Many organizations, responding to this ongoing loss, focus on individual species or certain taxa at high risk of extinction and endeavor to create protected areas for these species.

Such is the goal of the Alliance for Zero Extinction (AZE), a consortium of conservation organizations. The AZE in 2005 analyzed the extinction threat for IUCN Red List threatened species that have a single confined range. These analyses covered birds, amphibians, mammals, reptiles, and coniferous plants. The analysis then determined the extent to which the species' ranges were protected. Of the 595 that contained 794 AZE species (updated in 2010 to 920 species), only 203 (43%) were fully contained within protected areas; another 87 (15%) were partially within a protected area (Ricketts *et al.*, 2005) (Figure 1). Most sites were found in the tropics, with more than 350 sites found in Tropical Moist Forests. Of the 329 sites in the Americas, only 151 (45%) have some degree of protection; of the 250 sites covering 334 species in Central and South America (including the Caribbean), 40% have some degree of protection.

Formal Creation of Protected Areas

The most common approach to protection entails legal designation, typically by national or local governments, of an area for a particular purpose. This may entail governmental ownership or, in countries such as the United States, governmental management of public lands. It is not unusual for privately owned lands to be incorporated into protected areas, particularly in protected landscapes where existing farming or other land uses, known in the United States as inholdings, continue. In a few countries, notably the United States, effective protection has also been widely achieved through the establishment of conservation easements whereby owners agree to permanent legal restrictions on land use and activities on their land in exchange for significant tax benefits. The property remains in private hands or is held by land trusts (Kiesecker *et al.*, 2007).

Protection associated with private lands and with traditional land tenure enjoys minimal legal safeguards other than land-use zoning, water rights, and prohibition on trespass. Private protected areas are widespread under ownership of nongovernmental organizations, local communities, and commercial hunting or tourism operators (Beck *et al.*, 2004; Bernstein and Mitchell, 2005; Jones *et al.*, 2005). Traditional systems remain widespread, ranging from holy mountains in Mongolia to small fishery reserves across the Pacific Islands. Increasingly, such areas are being strengthened through legal recognition, either of the individual sites (such as the Islamic hema system in many Arabian grazing ranges) or of the communities rights to manage communal lands and waters. The Locally Managed Marine Area Network expanding across the Pacific, although community driven, has benefitted significantly from the development of policy at local, regional, country, and international levels to recognize local ownership and governance of marine resources. The assessment of the

Figure 1 Map of 595 sites of imminent species extinction. Yellow sites are either fully or partially contained within declared protected areas (203 and 87, respectively), and red sites are completely unprotected or have unknown protection status (257 and 48, respectively).

coverage and effectiveness of privately protected lands and traditional systems is challenging, and there is likely considerable underreporting in global data sets, but this is gradually improving.

International Approaches

The patterns and processes of nature rarely follow political boundaries; there are numerous cases where habitats, species, or populations cannot be adequately conserved in one country alone. Such efforts include bilateral funding, comanagement agreements such as transboundary protected areas (TBPAs), and the development and implementation of international agreements intended to improve global patterns and trends in conservation and protection. Three important global mechanisms provide for the identification and designation of protected areas directly:

- The 563 Biosphere Reserves in 110 countries are sites recognized under UNESCO's Man and the Biosphere Programme. They are nominated by nations for international recognition on a voluntary basis. The original intention was to develop a systematic approach to conservation by developing a biogeographically representative network of protected areas, although this aspect has received relatively little direct attention in recent years. One unique defining feature has been an effort to support complementary human use. Many sites are categorized into core, buffer, and transitional zones with differing levels of human use and access.
- Ramsar sites are protected areas recognized under the Convention on Wetlands of International Importance. Following a number of guidelines and criteria, member nations identify and protect important wetlands. In 2011 there were nearly 2000 designated sites covering 1.9 million km².
- World Heritage Sites are places of 'outstanding universal value' nominated by the 187 nations that have ratified the 1972 World Heritage Convention. Chosen to protect natural or cultural attributes or both, the sites are selected in a review process that determines if the importance of a given site 'transcends national boundaries.' The 923 sites selected as of 2011 (183 selected for natural attributes and 28 for natural and cultural attributes) are then protected by the member nations.

Finally, the influence of the 1993 CBD is considerable. The original text of this convention called generally for greater efforts to protect biodiversity; a subsequent agreement set tangible targets for effective conservation of 10% of each of the world's terrestrial ecological regions by 2010 and of marine regions by 2012. In 2011 these targets were reset:

Target 11: By 2020, at least 17 per cent of terrestrial and inland water areas, and 10 per cent of coastal and marine areas, especially areas of particular importance for biodiversity and ecosystem services, are conserved through effectively and equitably managed, ecologically representative and well connected systems of protected areas and other effective area-based conservation measures, and integrated into the wider landscapes and seascapes. (Convention on Biological Diversity, 2010)

Table 1 Total area of TBPA by region (TBPA, 2007)

<i>Region</i>	<i>TBPA area (km²)</i>
North America	1,511,627.08
Central and South America	1,424,697.66
Europe	188,153.30
Africa	931,617.95
Asia	570,505.86

Although many of these international agreements and conventions have some legal framework, effective enforcement mechanisms are typically weak and cases are very rarely brought before the multinational or international courts. Even so, a number of NGOs and site managers have used the high profile of international recognition as a tool to support protection. For many countries, national pride in international recognition can also lead to associated benefits from tourism, particularly for World Heritage Sites. In some cases there are also financial and other supporting mechanisms for international sites.

A TBPA straddles one or more national or provincial boundaries. Though the area is managed cooperatively and human-made barriers are removed, each country retains sovereignty over the area within its borders. According to the most recent official inventory (2007), there are 227 TBPAs incorporating 3043 individual protected areas and more than 4.6 million km² (Table 1).

Status: Where and How Much; Measures of Effectiveness

Introduction

The World Database on Protected Areas (WDPA) is the major source of information on protected areas. Maintained by the World Conservation Monitoring Centre of the United Nations Environmental Programme and the IUCN World Commission on Protected Areas, the database contains crucial information from national governments, nongovernmental organizations, academic institutions, and others. It is used for ecological gap analysis, environmental impact analysis, and other components of conservation decision-making by governments and the private sector. The WDPA is also used to report progress toward the United Nations Millennium Development Goals, specifically Goal 7, which seeks to ensure environmental sustainability, and toward the 2020 Biodiversity Target of the CBD, specifically subsidiary Targets 1.1 and 1.2, which call for protection of at least 17% of each of the world's ecological regions.

Global, Continental, and Country-Level Coverage

Protected area coverage has been rising steadily since 1950 (Figure 2) and has increased sharply since 1970. As of 2010, the total protected area stands at 13.4% of Earth's terrestrial surface (Coad *et al.*, 2009a, b). At a global level, this figure exceeds the CBD 2010 target of 10%, but there is

Figure 2 Global trend: cumulative global growth in the area of nationally designated protected areas (1872–2007). Total number of national sites = 113,962, of which 70,289 have establishment dates given in the WDPA.

Figure 3 Land protection by country.

considerable variation among countries, ecoregions, biomes, and realms, and this measure provides no indication of effectiveness or representativeness.

The 236 nations that submit data to the WDPA have an average of 13% terrestrial protection, but only 108 countries

have more than 10% protection (**Figure 3**). Twenty-nine countries have protected more than 25% of their land – including the very large and high biodiversity country of Brazil (28% protection) (UNEP-WCMC, 2010). Brazil also accounts for 74% of the land area added to protected status since 2003

Table 2 Regional land protection

<i>Region</i>	<i>Total area (000,000 km²)</i>	<i>Percentage protected area coverage</i>
South America	19.84	21.09
Central America	0.74	23.54
North America	27.54	17.93
East Asia	12.76	15.94
Eastern and Southern Africa	12.91	14.66
Europe	6.48	13.79
Australia/New Zealand	9.11	9.95
Western and Central Africa	13.33	10.33
North Africa and Middle East	13.08	8.37
North Eurasia	23.33	7.69
Southeast Asia	10.07	13.73
South Asia	4.87	7.09
Caribbean	0.88	14.69
Pacific	3.02	9.7
Antarctic	14.79	0.01

(Jenkins and Joppa, 2009). Very little land outside of Brazil has been protected since 2003.

The UNEP-WCMC recognizes 15 large geographic regions consisting of continents and subcontinents. Nine of the 15 have protected more than 10% of their lands (Table 2).

Protection by IUCN Category

Of the 110,000 protected areas in the WDPA database, approximately 40% are uncategorized (19.7% of the land area in database); some have not been assigned an IUCN protected area management classification or the designation information was not made available to the WDPA. There is also disagreement as to how to apply the categories to particular sites. Of the categorized 66,000 sites, 33,070 (2.24 million km²) falls into IUCN Category IV (habitat/species management area). Categories II (national park) and VI (protected area with sustainable use of natural resources) have a much lower number of protected areas (3731 and 3347, respectively), but they cover a greater total area – a combined total of 6.74 million km² (Table 3).

Terrestrial Habitats and Ecosystem Protection

To assess the representativeness of protected areas, which measures the extent to which biodiversity is actually protected, numerous studies have used WDPA data to evaluate progress toward the CBD targets, all using a global biogeographic framework known as the World Wildlife Fund Ecoregions (Olson *et al.*, 2001) that divides terrestrial areas into realms, biomes, and, at the finest level, ecoregions. More than 120,000 records in the WDPA are difficult to use, interpreting results are challenging. Some countries have not fully classified or have reclassified their protected lands. The most prominent example is the United States, which initially included all the National Forests and National Grasslands, totaling some 77.7 million ha. By 2009, the Forest Service had removed all of the National Forests – more than 76 million ha – from the WDPA (Coad *et al.*, 2009b). This change affected the amount of

Table 3 IUCN categories: Area and percentage of nationally designated sites by IUCN management category

<i>IUCN category</i>	<i>Area protected (million km²)</i>	<i>Percentage of total area of sites with assigned IUCN category</i>
I	1.78	1.35
II	3.37	2.56
III	0.22	0.17
IV	2.24	1.70

VI	3.37	2.56
Other	3.33	2.53
All PAs	16.94	12.85

PA, protected area.

temperate coniferous forests globally protected. Countries can refuse to allow data to be included for various reasons. Some countries provide imprecise data about location and boundaries. Location data can be inaccurate because countries often report sites as points and the boundaries are assumed to be a circle centering on that point and representing the reported size of the site. When adjacent to another protected site, some area might be lost in the analysis where overlap occurs, even though the two sites do not actually overlap. Imprecise location data can also be a problem in ecoregional analyses, because some part of the protected area may actually be in a different ecoregion than that represented by the assumed boundaries. There is also a debate about the inclusion of biosphere reserves, as, in some countries, these have no legal status and protection may be limited (Table 4).

Biogeographic Realms

Biogeographic realms represent the broadest scale patterns of variation in terrestrial biodiversity. The targets set under the CBD do not include realms. Nonetheless, the extent to which realms have been protected is informative in assessing broad-scale patterns of protection. At this level, 10% protection has been achieved in five of the seven realms (Coad *et al.*, 2009b).

Biomes

Although realms capture major patterns of evolutionary uniqueness, biomes represent physiognomic diversity, capturing the major habitat regions of the planet. Only three of 14 biomes have less than 10% of biome area protected (Coad *et al.*, 2009b). Using the WDPA 2009 data set, Jenkins and Joppa (2009) found that temperate grasslands were the least protected and most severely converted, with less than 4% protected (Table 5 and Figure 4). In contrast, an earlier study found that flooded grasslands, montane grasslands, and tropical moist forests each had more than 20% protection (Hoekstra *et al.*, 2005). Since 2006 this disparity has increased, especially within tropical systems, reflecting a continued emphasis on protecting tropical systems. Encouragingly, protection in the Mediterranean Biome has increased from 5 to 7.5% – a sizeable increase reflecting the work of many conservation organizations and the success of prioritizing an ecosystem.

Because biomes are found in multiple realms, simple biome statistics may overlook major spatial variation in protection efforts. Given the unique evolutionary history of different realms, it is critical to consider both realms and biomes to obtain even a simple measure of representative protection. Jenkins and Joppa (2009) found that 46% of biomes within each realm remain below the 10% threshold.

Table 4 Protected area coverage of WWF realms

Realm	Percentage protection (%)
Neotropic (Central and South America)	27.1
Afrotropic (sub-Saharan Africa)	15.8
Nearctic (North Mexico, USA, and Canada)	12.2
Australasia (including New Guinea)	11.8
Palaearctic (Northern Africa and Eurasia)	11.1
Indo-Malay (South and Southeast Asia)	9.9
Oceania (Pacific Islands)	6.1

Terrestrial Ecoregion Protection

Coad *et al.* (2009b) found that 54% (447 out of 821) of ecoregions met or exceeded the 2010 CBD 10% target (Figure 5).

Forests

Using WDPA 2008 data, Schmitt *et al.* (2009) calculated the protection percentages for each WWF forest ecoregion (Table 6 and Figure 6). Globally, 18.8% of forest cover was protected; only Oceania did not meet the 10% threshold for forest protection. The neotropical realm had the highest level of forest protection, at 34% (Table 6 and Figure 7).

Dry and Subhumid Lands

The Millennium Assessment identified four types of drylands (dry subhumid, semiarid, arid, and hyperarid) and used the following WWF biomes to assess the extent of protection: deserts and xeric shrublands, temperate grasslands, tropical and subtropical grasslands, and Mediterranean forests and shrublands (Safriel and Adeel, 2005). Although three of the four biomes have more than 10% protection (Table 7), 130 of the 227 dryland ecoregions (57%) are below the 10% threshold (Coad *et al.*, 2009b).

Mountains

In 2002, UNEP-WCMC defined mountain extent using criteria such as elevation and slope (Blyth *et al.*, 2002). A recent analysis using this data set found that mountain areas cover 39.3 million km² (26.5%) of the world's terrestrial area. By the end of 2009, nationally designated protected areas (PAs) covered 5.7 km² (14.3%) of the world's mountain areas outside Antarctica. Mountain PAs thus comprise 17.3 million km² (32.5%) of the world's total terrestrial protected area coverage. Mountain protected area coverage has increased globally by 21% since 1990. Out of 198 countries with mountain areas, 87 (43.9%) still had less than 10% of their mountain areas protected, whereas 18 (9.1%) had more than 50% protected area. In 87 of the 728 ecoregions with mountain areas, more than 50% of the mountain area was protected. In 16 (2.2%), mountain protection reached levels of 90–100%. However,

Figure 4 Realm-Biome Protection Percentage – map created from data derived.

Figure 5 WWF Ecoregion protection percentage.

332 (45.6%) had less than 10% of mountain areas protected; 68 (9.3%) had no mountain areas protected at all (Rodríguez-Rodríguez *et al.*, 2010).

Islands

Very little work has been done to determine the protected status of island terrestrial area. Using the [WDPA 2009](#) and a

global country data set ([ESRI, 2008](#)), a global assessment of marine islands (171 countries have such islands) reveals a protection percentage of 29.3% of terrestrial area (Boucher, 2011, unpub.). This figure includes Greenland, which is almost 40% of the combined island area and has 51.4% protection. With the removal of Greenland, global island percentage protection drops to 15%. For tropical islands (with 118 countries

represented), protection percentage drops to 11.5%. When refined to Pacific tropical islands, the protection percentage drops to only 2.5%. Individually, 58 of the 118 tropical island countries fall below the CBD 2010 target of 10%. For some islands that host high biological diversity, protection percentages are low, such as Puerto Rico (7.7%), New Caledonia (5.5%), Madagascar (4.2%), Fiji (1%), and Haiti (under 1%). Tropical islands that exceed 10% protection include Cuba (12%), the Dominican Republic (15%), Jamaica (19.7%), the Seychelles (31%), and the Ecuadorian islands, including the Galapagos Islands (86%) (Boucher 2011, unpub.).

Marine Protection

Marine protection has always lagged far behind terrestrial protection, likely as a result both of lack of awareness and of

the challenges of legal designation and implementation, particularly in the high seas, which make up some 45% of the entire planet. Through increased awareness and focused effort, both national and international, marine protection has increased rapidly (more than 280% since 2003) in recent years to 5880 sites in 2010 (Spalding *et al.*, 2010), with 4.7 million km² protected (1.31% of the global ocean). This protection is concentrated within 200 nmi of coastlines, where some 3.21% falls within Marine Protected Areas (MPAs).

Most conservation attention is concentrated in very near-shore waters, so although 4.32% of shallower continental shelf waters (less than 200 m deep) fall within MPAs, only 1.06% of areas beyond the continental shelf are covered. Only 12 of 190 states and territories have MPA coverage of their territorial waters at or above 10% (Spalding *et al.*, 2010).

From a biogeographic perspective, MPA coverage is also very uneven and does not adequately represent all ecoregions and habitats even in coastal areas. Marine ecoregions have been developed for continental shelf waters in a process analogous to terrestrial systems (Spalding *et al.*, 2007), and of the 232 marine ecoregions, 102 (44%) have less than 1% coverage, whereas only 44 (19%) have more than 10% protection. Some MPAs are extremely large; 11 of them exceed 100,000 km² in size and comprise 60% of the global coverage. The high sea areas (beyond 200 nmi) from coastlines remain almost entirely unprotected.

Table 6 Percentage forest protection by WWF realm

Realm	Percentage forest protection	Percentage ecoregions below 10%
Afrotropic	16.0	75.8
Australasia	18.1	46.8
Indo-Malay	16.6	51.5
Nearctic	17.5	70.2
Neotropic	34.2	62.1
Oceania	8.2	50.0
Palaearctic	10.5	82.0

Freshwater Ecosystems

Freshwater ecosystems, also called inland waters, and their dependent species are among the most imperiled ecosystems in the world (Millennium Ecosystem Assessment, 2005).

Figure 6 Forest protection – using a combination of GLC2000, MODIS05 VCF, and analyzed with WDPA 2008 data.

Figure 7 MPA coverage by marine ecoregion (percentages represent continental shelf area only).

Table 7 Protection of dryland biomes

WWF biome	Area (km ²)	Percentage of area protected	Number of ecoregions in biome	Percentage of ecoregions meeting the 10% target
Deserts and xeric shrublands	27,984,645	10.8	96	43
Temperate grasslands, savannas, and shrublands	10,104,080	4.1	43	9
Mediterranean forests, woodlands, and scrub	3,227,266	10.2	39	54
Tropical and subtropical grasslands, savannas, and shrublands	20,295,424	15.9	49	63

According to the IUCN Red List of Threatened Species, one-third of amphibians and freshwater mammal species and one-fourth of the more than 240 freshwater turtle species are threatened with extinction. This situation is not surprising, as humans have settled in and around watercourses and relied on them for millennia. Humans have used freshwater ecosystems as sources of food and water, for transportation, and for waste disposal. As a consequence, many of the world's waterways have been heavily altered, impacting both freshwater species and the services derived from aquatic ecosystems, such as water supply, flood protection, and aquifer recharge. These nonmarketed services actually have a higher value than the marketed benefits of conversion of natural habitats to other uses (Millennium Ecosystem Assessment, 2005; Balmford *et al.*, 2002).

Many of these services are often unprotected, and their loss usually comes at a high price. There is ample evidence that the cost to restore key ecosystem services after degradation far

exceeds the cost of protecting these services; in a comprehensive review of river restoration efforts in the United States, Bernhardt *et al.* (2005) point to the more than US\$14 billion spent rehabilitating degraded streams in the United States since 1990.

Despite the value of services provided and the degree of imperilment of freshwater ecosystems, protection and conservation of inland waters has come at a slow pace when compared to the protection of terrestrial and, more recently, marine ecosystems. For decades, protected areas have been a key conservation strategy for terrestrial habitats, but for inland aquatic habitats such as rivers, lakes, marshes, and groundwater aquifers, this has not been the case. The traditional approach of fencing off an area for protection and management is unlikely and impractical for many aquatic habitats, particularly those with linear features, such as rivers and streams. Terrestrial protected areas do contain many and varied inland aquatic habitats, but many freshwater habitats and species

have not benefited much from surrounding or adjacent terrestrial protected areas largely because those protected areas have not been designed or managed for aquatic ecosystems and because they are especially vulnerable to pressures occurring outside the protected area (Abell *et al.*, 2007). Many terrestrial protected areas afford only partial protection to aquatic habitats, and important issues such as longitudinal and lateral connectivity and maintenance of essential hydrological processes (i.e., environmental flows) are not considered. Moreover, rivers are often used for the sole purpose of demarcating a terrestrial protected area boundary and are not integrated into the protected area's conservation and management objectives.

The only clear exception is the protection of aquatic habitats with defined surface areas, such as lakes, lagoons, marshes, and other wetlands. Under Ramsar, signatory countries have protected 1919 coastal and inland wetland sites with a total surface area of 186.7 million ha. Together these sites comprise the Ramsar List of Wetlands of International Importance, with the overarching goal to "maintain an international network of wetlands which are important for the conservation of global biological diversity and for sustaining human life through the maintenance of their ecosystem components, processes and benefits/services" (Ramsar). As of 2011, Ramsar had 160 contracting countries that could designate Ramsar sites and in doing so commit to protecting them from development, pollution, and other pressures (Figures 8 and 9).

For surface water bodies, establishing protected areas continues to be a customary conservation approach, but effective design and management has to include protection, or at a minimum, sound management of important features and processes that are essential to sustaining the wetlands being protected. These key features include rivers or ground-water aquifers that feed into the particular lake or wetland but are often located outside the protected area boundary.

Protecting linear features like rivers and stream by means of a protected area is not always feasible. Only a handful of countries including the United States, Canada, Australia, and New Zealand afford certain protections to entire rivers or portions of rivers. The United States designates as Wild and Scenic Rivers 12,560 miles of rivers or portions of rivers with outstanding natural, cultural, and recreational values that should be sustained in a free-flowing condition for the enjoyment of present and future generations (National Wild and Scenic Rivers Act of 1968). These rivers are federally protected from dams and other in-stream modifications. The law stipulates that each designated river be administered by either a federal or a state agency, but protection relies heavily on voluntary stewardship among stakeholders and regulatory programs by different governments agencies. Designation does not affect existing water rights or private property rights.

The Canadian Heritage Rivers System (CHRS) protects 41 rivers across Canada (CHRS, 2011). This government-supported stakeholder participatory program aims to promote, protect, and enhance Canada's river heritage. Canadian Heritage Rivers must meet established criteria regarding natural, cultural, and recreational values and be vetted through a rigorous and lengthy process. Public support is essential. Heritage River designation carries a commitment to protect its heritage values and integrity via a management plan or heritage strategy (CHRS, 2011). The CHRS relies on voluntary participation, community involvement, and collaboration between government agencies and stakeholders. The different provincial, federal, and territorial government agencies retain their traditional jurisdictional powers and management responsibilities; the CHRS does not have overall authority.

New Zealand has 13 river catchments and two coastal lakes largely protected through its Water Conservation Orders (New Zealand Ministry of the Environment, 2011). Water

Figure 8 Ramsar wetland area protection by freshwater ecoregion (in km²).

Figure 9 Ramsar wetland percentage area by freshwater ecoregion.

Conservation Orders aim to protect water bodies with outstanding natural, scenic, recreational, or cultural value (New Zealand Ministry of the Environment, 2011). The Minister of the Environment grants the order after a thorough review by an appointed special tribunal with a determined period for stakeholder comment; if granted, the order can restrict or prohibit new water abstractions, discharges, and other uses impacting the water body. Once an order is awarded, regional councils must modify their plans to comport with the order's provisions.

In Australia, the states of Victoria, Queensland, and New South Wales have similar river protection legislation. Queensland passed its Wild Rivers Act in 2005, and since then has declared 10 rivers as 'Wild Rivers.' The aim of the 2005 Act is to preserve those rivers whose natural values are intact or almost intact – that is, they retain essential riverine processes (Queensland Environment and Resource Management, 2011). A Wild River Declaration restricts and sets conditions for new development activities that may impact the river's natural values, such as water withdrawals, intensive land uses in the wild river area, and in-stream infrastructure projects. The State of Victoria, via its Heritage Rivers Act of 1992, has 18 Heritage Rivers listed for protection; however, according to a review by Nevill and Phillips (2004), 13 years later, "all river management plans remain as drafts without the required ministerial endorsement." The State of New South Wales has listed six rivers as 'Wild Rivers' because of their near-pristine condition; all lie within existing terrestrial protected areas" (NSW Office of Environment and Heritage, 2011).

Groundwater ecosystems enjoy even less protection than rivers. Many countries lack a basic inventory of groundwater aquifers, their condition, or how they feed into or connect to surface water bodies. Water quality legislation such as the U.S. Clean Water Act and the European Water Framework Directive provides some piecemeal protection to ground

waters, most commonly by restricting in-stream flow uses in surface waters (Aldus and Bach, 2011). Fewer policies protect groundwater-dependent springs, wetlands, or groundwater aquifers.

Groundwater ecosystems and rivers, particularly the middle reaches and floodplains, are underrepresented in the global protected areas network, but figures showing exactly how underrepresented they are have been hard to come by. A key limitation has been the lack of inventory and assessment of freshwater ecosystems and their condition, even at the national level. This limitation has hindered the tracking of progress of individual countries toward their commitments under the CBD. The CBD in 2004 called on parties to "establish and maintain comprehensive, adequate and representative systems of protected inland water ecosystems within the framework of integrated catchment/watershed/river-basin management" (CBD Conference of the Parties, 2004a, b). Yet when the CBD 2004 Programme of Work on Protected Areas called for conservation of at least 10% of each of the world's ecological regions by 2010 for terrestrial ecosystems, it made no mention of inland waters as it was assumed that these habitats would be covered by the terrestrial target because they encompass riverine, lacustrine, wetland, and groundwater ecosystems.

The assumption that terrestrial protected areas protect the freshwater ecosystems found within them is therefore ingrained in the thinking and approach of most nations and of the CBD. Until recently, there was no global spatially explicit database of river networks at a resolution sufficient to allow for a detailed estimation of how much protection – at least in terms of coverage – terrestrial protected areas convey to waterways. In 2010, however, WWF in collaboration with McGill University and UNEP-WCMC released an assessment of the extent of coverage of rivers by protected areas by calculating both the length of rivers that lie within protected areas and the length of rivers that have their entire upstream

catchments under protection (WWF, 2010). This assessment showed that 69% of the world's rivers were without protected areas in their upstream catchment and that smaller headwater streams were more protected at catchment level than were larger rivers. The analysis therefore pointed to opportunities to increase the representation of freshwater ecosystems in the global protected area network. The analysis revealed important regional differences. Central and South America led the way in river protection, both at river length within protected areas and at upstream catchment levels. Asia, North America, and Europe/Middle East had fewer river miles and upstream catchment areas protected (WWF, 2010). This first estimate of river coverage provides a sense of how many lotic ecosystems could be protected if the management of the existing protected area network were tailored to address freshwaters but gives no indication of how protected areas actually protect freshwater processes and species.

Protected areas can and do work for freshwaters, but proper design and management are essential. Protecting freshwater ecosystems requires new approaches that incorporate the connectivity of freshwater systems and their key processes, such as spring peak flows that cue aquatic species to migrate, reproduce, and feed. Many of these approaches exist but are usually not considered within a protected area framework. Zoning rules, such as establishing riparian buffers to control runoff, reduce bank erosion, and provide shade, are in effect in many basins but are not *per se* protected areas. Water recharge areas or fishing reserves are other examples of protection that contribute to the conservation of freshwater habitats. Protected area design needs to include such measures, and protected area management needs to look beyond the terrestrial park boundary in order to reduce the rate of loss of freshwater species and the habitats upon which they depend.

Condition

The number of protected areas, the cumulative area protected, or even the representativeness of biomes or ecoregions say nothing about the effectiveness of protected areas in achieving their intended purposes. The CBD also calls for protected areas to be effective and equitably managed – metrics that cannot be assessed simply through measures of total coverage. Condition is hard to measure directly without extensive and time-consuming ground surveys, but there are indicators of the function of protected areas.

'Paper parks' are areas that have been officially gazetted as protected but have been given little or no active management (Brandon *et al.*, 1998). Some paper parks may be secure by virtue of remoteness, but in most cases, the condition of these protected areas will degrade due to encroachment for natural resource extraction or conversion to agriculture. In Brazil, for instance, 34% of protected areas have only one or two staffers and 25% of others are entirely unstaffed (Balazina, 2011).

Protected area failure differs from paper parks. Failure occurs when the protected area does not attain its specific goals for its stated establishment, even if managed as planned. The management plan may not have been capable of producing the intended outcome, it may not have been

implemented properly, or enforcement against encroachment and prohibited uses may have failed.

Bruner *et al.* (2001) used questionnaires to assess the extent of land clearing, logging, hunting, fire, and grazing in protected areas. Of 93 parks in 22 tropical countries, 43% had had no net clearing after having been established. Even those heavily impacted by logging and hunting were in considerably better condition than the surrounding areas.

Bruner concludes that the claim that most parks in tropical countries are 'paper parks' – that is, parks in name only – is not substantiated, but in fact, the parks studied were not paper parks. All had guards, and effectiveness was most strongly correlated with the density of guards.

Human intervention may be needed to maintain natural conditions: artificial flooding regimes to maintain wetlands, native species planting, or invasives removal are all management interventions to maintain 'natural' systems in any site and particularly in small, isolated sites. Sites with only partial restrictions on use and activities may provide critical buffers or corridors to connect more strictly protected areas.

Conversion of Land in Protected Areas

Despite legal protection and active management, areas under protection, or some parts of those areas, are sometimes converted from their natural state to some form of human use such as agriculture or settlement. Using GLOBCOVER 2008 and WDPA 2009, the amount of protected area converted from a natural state was calculated. This global overview reveals that 2.4 million km² (9.2%) of the area under protection has been converted. This analysis does not evaluate fine-scale or subtle changes such as grazing or selective logging and does not exclude a small number of protected areas that may have been established on existing converted lands. No biome is untouched (Table 8). Conversion of protected areas ranges from below 1% in tundra to 72% in temperate grasslands.

Ongoing and Emerging Threats

Generally

Threats to protected areas abound, mostly in the form of external pressures that manifest as encroachment and result in deterioration. Protected areas often encompass viable agricultural land and rich natural and mineral resources, and so are very attractive to those living near them. Not surprisingly, the worst threats are habitat degradation and loss due to agricultural incursion, invasive species, and exploitation of natural and mineral resources, such as illegal logging, poaching of wildlife, overfishing, and mining. *Ex situ* threats such as pollution and climate change pose challenges to even the best managed PAs.

Inherent challenges include reserve design, isolation, and fragmentation. To be effective, the protected area's design and management must address the threats to the area and the biodiversity it supports. If essential management activities such as monitoring the health of habitats, enforcing the rules of the protected area, and working with local people to balance their needs and aspirations with the need to protect nature are not completely successful, threats can cause degradation even to well-designed areas.

Table 8 Percentage and area (km²) of protected area conserved for human use (agriculture/urban), by WWF biome

WWF biome	Percentage protection converted (%)	Area (km ²) protected converted
Tropical and subtropical moist broadleaf forests	9.9	411,121
Tropical and subtropical dry broadleaf forests	44.5	147,796
Tropical and subtropical coniferous forests	18.4	8,779
Temperate broadleaf and mixed forests	27.6	341,578
Temperate coniferous forests	7.5	43,353
Boreal forests/taiga	0.4	6,282
Tropical grasslands, savannas, and shrublands	22.2	599,598
Temperate grasslands, savannas, and shrublands	72.3	272,897
Flooded grasslands and savannas	12.4	39,860
Montane grasslands and shrublands	28.9	380,595
Tundra	0.02	405
Mediterranean forests, woodlands, and scrub	18.5	43,919
Deserts and xeric shrublands	3.9	100,827
Mangroves	17.9	16,172

Encroachment

Encroachment into protected areas takes many forms, from large-scale resource extraction to fine-scale incursion such as cattle grazing and selective logging. In many countries, roads that provide entry into protected areas become pathways for both large and small encroachment (Cropper *et al.*, 2001). Human encroachment can also move invasive species into a protected area. The pressure of growing populations in the surrounding area may lead to encroachment (Birner *et al.*, 2006). Although this is especially true in developing countries, encroachment occurs in developed countries, too.

Of all the threats to protected areas in forested regions, deforestation, be it clear-cutting or selective logging, is the most pressing and widespread. Efforts to curb deforestation have had mixed results. Success is heavily tied to enforcement of the legal boundaries, which in turn requires political will and stability. The extent of deforestation in protected areas can be dramatic. An analysis of satellite imagery of the protected areas of Kalimantan in Indonesian Borneo found that the lowland PAs had been reduced by 63% (18,500 km²), primarily by intensive logging (Curran *et al.*, 2004).

Mining

Balancing the economic needs of a country with conservation needs is always tricky. As countries grow, more and more resources, including underground minerals that can be very valuable, are required to fuel this growth. Mining entails the clearing of land for infrastructure, such as roads, housing, and in some cases, surface access to minerals. It also contaminates freshwater with toxins from the tailings. Miners may also poach wildlife.

The extent of mining in protected areas is poorly studied. The World Bank in 2010 initiated a study of artisanal mining in protected areas in Liberia and Gabon, and preliminary results include the lack of economic alternatives and risk to the environment through mercury use (PROFOR, 2011). In May 2011, the WWF's Central Africa Programme Office and World Wildlife Fund–U.S. announced the launching of a new project to address the impacts of artisanal and small-scale mining in and around the world's protected areas.

Industrial mining is conducted in some protected areas, in some cases as a preexisting and grandfathered use and in other cases by design. For instance, the Government of Canada together with the governments of the Northwest Territories and the Yukon has developed Terms of Reference for the Mineral and Energy Resource Assessment (MERA) process for proposed national parks in northern Canada. In some countries, including French Guiana, Finland, Indonesia, New Zealand, and Australia, mining companies are pushing governments to open protected areas to industrial mining activity.

Poaching and Bush Meat

Wildlife has long been taken as a protein source for humans. As growing human populations delete wildlife populations outside protected areas, people turn to poaching wildlife within protected areas. New roads, often built for timber extraction, facilitate access into remote or inaccessible areas; hunting for food has become a major problem in protected areas. Wildlife in many places is also a source of income, as bushmeat for local and even international markets or in illegal trade such as that of elephant tusks and rhino horns. Many protected areas have now become vital sanctuaries for what were wide-ranging species such as elephants and rhinos. Increased law enforcement in and around protected areas alone seems inadequate to stop poaching. Unless and until local people benefit more from the nonconsumptive value of wildlife and develop reliable sources of protein and income, even the largest, well-planned protected area may be incapable of protecting this component of its biological diversity.

Isolation

As the world develops, urban areas grow, land is cleared for agriculture, forests are logged, and myriad other human activities alter or eliminate natural areas. Protected areas that were once part of a larger landscape become islands in a sea of human development. This isolation undermines the ecological integrity of the ecosystems and the survival of the species that were to be protected. Isolation poses a threat to the long-term viability of wildlife and especially migrations of large mammals (Newmark, 2008).

With the loss of unprotected natural habitat, the protected area, in some extreme cases, remains the last fragment of natural habitat. This is especially true for tropical forests, which contain the majority of the world's terrestrial biodiversity. In an assessment of forest cover in and around 198 tropical protected areas, DeFries *et al.* (2005) found that of the protected areas studied, 69% in moist tropical forests and 54% in dry forests experienced a decline in forest habitat within 50 km of their periphery, with 28% and 29%, respectively, declining by more than 5% of the forest area. Although this loss occurred in most tropical areas, it was particularly high in southern and southeast Asia. Other studies show that isolation is occurring in the temperate and boreal regions as well. Young *et al.* (2006) found that even in the enormous boreal region of Canada, protected areas are becoming increasingly isolated as forests outside the protected areas are logged and fragmented.

Funding

Creating protected areas and managing them effectively require money. Only a few countries have managed to assure long-term, sustainable financing for protected areas. This funding gap is particularly acute in developing countries (De Oliveira, 2002) and for marine protected areas (Wells, 2008). What is needed is a way to find new and sustainable financial resources to supplement government funding for existing protected areas.

Tourism

Tourism is a mixed blessing for protected areas. Entry fees and hospitality and souvenir concessions generate income that provides much needed funds to run protected areas. Tourism to protected areas has been growing rapidly, so much so that in some countries, tourism has become an important part of their economies. In Kenya, for instance, tourism, which centers on the country's large parks, is the third highest contributor to gross domestic product (Messerli *et al.*, 2010). Tourism can also have a negative side, as it requires facilities and infrastructure to support the industry. Tourism can put considerable pressure on natural ecosystems and wildlife ('loving nature to death') (Bushell and Eagles, 2007).

Trends in Protected Area Conservation

Accretion in Number and Size of Areas

Opportunities to designate new protected areas or expand existing protected areas, or increase connectivity, will diminish due to population growth and the associated demands for natural resources, including arable land, energy, and water. Within years, or a few decades at most, the world's terrestrial surface will largely be assigned in terms of ownership and use, with marine spaces lagging only a short way behind. Protected areas will be by far the largest and most important tool for safeguarding nature. It also seems likely that the social and economic value of this estate will be more clearly established and will be far greater than currently perceived.

Some authors suggest that designation will continue at relatively rapid rates in the near future. Some countries still

have relatively large areas of important biodiversity outside of protected areas. These areas are largely unmanaged. McDonald and Boucher (2010) suggest that the future of the protected area accretion appears to be positive. They regressed country-level protection rates from 1950 to 2005 against other available country-level time-series data. Variables positively correlated to protected area increase were high per capita gross domestic product, high levels of primary education, and a more stable and independent political structure. Poverty reduction is actually a more important factor in predicting the addition of protected area than is the biodiversity significance of the region, which attracts external pressure and funding to create protected areas. The analysis suggests that by 2030, global land protection could reach 15–29%, with more new land being protected in the next 20 years than in the previous 20 years.

The effectiveness of additional protected areas may be hindered by the lack of available buffer area. In other words, new protected areas may be isolated and expanded protected areas may be fragmented when created. In fact, protected areas may actually attract development (Wade and Theobald, 2010). After investigating spatially explicit data sets and 304 protected areas, Wittemyer *et al.* (2008) concluded that population is growing more rapidly (double the rural average rate) close to the protected areas than in more distant areas. Joppa *et al.* (2009) used the same data as Wittemyer *et al.* (2008) but concluded that the observed population expansion likely resulted from nearby population centers and that the growth observed near protected areas did not differ from average rural growth.

International carbon markets and the payments for the maintenance or enhancement of natural carbon stocks may facilitate large-scale accretion of protected areas. The United Nations Reducing Emissions from Deforestation and Forest Degradation (REDD) program should lead to considerable payment flows to tropical forest countries for the avoidance of deforestation. The REDD discussions have focused on areas outside current protected areas as these are the locations where extensive loss and degradation are occurring (Asner, 2011; Sandbrook *et al.*, 2010). There is also considerable interest in the development of similar mechanisms for coastal systems to protect the 'blue carbon' contained both in living biomass and in the soils of mangroves, saltmarshes, and seagrass beds; the high productivity of these systems has high value for carbon capture and storage (Crooks *et al.*, 2011; Laffoley and Grimsditch, 2009).

The marine environment still represents a conservation frontier. It has been suggested that the largest gains in protected area coverage will be in the marine realms despite the high costs and challenges of management. Some 50% of the oceans lie beyond any national jurisdiction, requiring the development of policies and approaches for management of the 'high seas.' One possible advantage for marine conservation is that issues of ownership and use rights are generally simpler than on land. This has meant that large-scale approaches, such as ecosystem-based management and ocean zoning, are perhaps more easy to implement, although even here the challenge of integrating the needs of multiple sectors remains considerable (Agardy *et al.*, 2011; Halpern *et al.*, 2008; Ruckelshaus *et al.*, 2008).

Loss of Existing Protected Areas

In a recent analysis, Mascia and Pailler (2010) identified at least 89 instances (in 27 countries) since 1900 of protected area downgrading (decrease in legal restriction), downsizing, and degazetting (PADDD). The extent of PADDD is unknown; Mascia and Pailler (2010), citing Zimmerer *et al.* (2004), report that nine countries (Botswana, Cameroon, Gabon, Ghana, Guinea-Bissau, Luxembourg, Pakistan, Somalia, and Togo) experienced a 5–60% decline in protected area coverage between 1985 and 1997. Some proposals to downgrade, downsize, or degazette have failed. Reasons for PADDD vary widely, but often center on access to and use of natural resources. In some cases, the official action merely recognized the failure of a protected area.

Shift to Multiple-Use Areas

New protected areas will tend increasingly to be multiple-use protected areas (IUCN Categories V–VI) rather than strict protection (IUCN Categories I–IV). This result is in accord with studies that have noted the rise of multiple-use PAs (Naughton-Treves *et al.*, 2005). Another facet of this shift is the planned inclusion of indigenous groups or communities living in or near protected areas. In protected area theory and practice, the trend is away from the traditional concept of protecting areas by excluding people, which in its extreme form entailed the forced removal of people living in the area. Governments and conservation organizations now attempt to work with people who live in or near protected areas. Conservationists realize that failing to involve the local people often leads to failure in the long-term because those people need a form of economic activity to replace their use of the natural resources in the area.

Protected Area Management in the Context of the Surrounding Landscape

Protected areas will clearly remain a critical cornerstone of conservation efforts, but it seems likely that the boundaries between protected area approaches and other natural resource management measures will become increasingly blurred. In part, this is being driven by the growing realization that the need to manage natural resources at effective ecological scales can require natural resource management outside protected areas. Further impetus may come from the growing recognition of the value of ecosystem services. This is likely to encourage many nontraditional conservation partners, including utilities, agriculture, tourism, commercial fisheries, and others who may call for the protection of natural resources on strictly utilitarian grounds: to safeguard water supplies, reduce flood risks, or protect stocks. Sustainable management of natural resources across a matrix of protected areas and unprotected areas, beyond designated buffer zones (where they exist), would likely enhance the effectiveness of protected areas.

Glossary

Conservation Maintenance of the diversity of living organisms, their habitats and the inter-relationships among organisms and their environment.

Ex situ conservation Literally, away from the site or location; in this context means the conservation of components of biological diversity outside their natural habitats, for example, botanic gardens, seed banks.

Herbaria Collections of preserved plant and fungal specimens and their associated data. They are concerned

primarily with scientific research and documenting the vast diversity of plant and fungal life.

In situ conservation Literally, in or at the site or location; in this context means the conservation of ecosystems and natural habitats and the maintenance and recovery of viable populations of species in their natural surroundings.

Seed banks Seeds are stored in conditions of low moisture and temperature. This technique is used for orthodox seeds of crops and wild species.

Introduction

Over the past few decades, botanic gardens throughout the world have undergone a remarkable transformation. As the greatest repositories of living plant collections worldwide, their importance and roles are better understood and appreciated by increasingly wide audiences. Many botanic gardens have been reinvigorated and rejuvenated to undertake a wide range of new tasks, particularly in education and plant conservation. The contribution of botanic gardens to cultural development, economic progress, and commercial expansion has been of great significance to many countries throughout the world over the past four centuries.

In the last 20–30 years, there has been a renaissance in botanic gardens worldwide, largely as a result of the developing concern for biodiversity loss and the need for many more institutions to become active in plant resources conservation. There has also been a corresponding rise in botanic garden involvement in research and conservation of the floras of the regions or countries in which they are situated.

Defining the Botanic Garden

There are no formal criteria or general agreement as to what constitutes a botanic garden. The lack of a very clear definition has blurred the edges between what are public parks or private collections and what are true scientifically based botanic gardens. In some instances, a garden has retained the name 'botanic' for historic reasons. Some or even most of the plant collection may survive, but often all the scientific activities have ceased and documentation has been lost. One might argue for the removal of these from a global list of botanic gardens. However, Wyse Jackson (1999) explains that it is precisely these institutions in many parts of the world that are currently being revived, redeveloped, and reestablished to become potentially important botanical centers.

An early definition of a botanic garden given by the International Association of Botanic Gardens was '...a botanic garden or arboretum is one open to the public and in which the plants are labelled' (IABG 1963 cited in Wyse Jackson, 1999). However, this definition fails to recognize the complexities of these institutions. *The Botanic Gardens Conservation Strategy* (IUCN-BGCS and WWF, 1989) introduced a wider view by presenting a list of characteristics defining a botanic garden that incorporate many of the diverse roles that these institutions now undertake. These defining characteristics included:

- adequate labeling of the plants
- an underlying scientific basis for the collections
- communication of information to other gardens, institutions, organizations, and the public
- exchange of seeds or other materials with other botanic gardens, arboreta, or research stations (within the guidelines of international conventions and national laws and customs regulations)
- Long-term commitment to, and responsibility for, the maintenance of plant collections
- maintenance of research programs in plant taxonomy in associated herbaria
- monitoring of the plants in the collection
- open to the public
- promoting conservation through extension and environmental education activities
- proper documentation of the collections, including wild origin
- undertaking scientific or technical research on plants in the collections (IUCN-BGCS and WWF, 1989, p 5).

This list does not, however, constitute a complete list of all the activities undertaken by botanic gardens. There are many institutions, which are recognized as botanic gardens, but often their work addresses only some of these criteria. The most widely used definition of a botanic garden is that adopted by Botanic Gardens Conservation International

(BGCI) in its *International Agenda for Botanic Gardens in Conservation* (Wyse Jackson, 1999, p 27 cited in Wyse Jackson and Sutherland, 2000, p. 12). BGCI suggests this definition encompasses the spirit of a true botanic garden:

'Botanic gardens are institutions holding documented collections of living plants for the purposes of scientific research, conservation, display, and education.'

Within the context of this article, the use of the term 'botanic gardens' should be interpreted to include arboreta and other specialized plant collections. In some parts of the world, the term botanical garden is used, rather than botanic garden. These can and are used interchangeably and both are correct.

Types of Botanic Gardens

Within the definition of a botanic garden given, a great diversity of institutions may be included, ranging from large gardens with several hundred staff and a wide range of activities, to small institutions with limited resources and activities.

A diverse range of organizations and administrations manage botanic gardens. Many are state administered or managed by regional or local authorities and receive public funding. About one quarter of the world's botanic gardens belong to universities and other research institutes for higher education and a relatively small proportion are private. A fast growing sector in the botanic gardens world is in the area of community botanic gardens, particularly in such countries as Australia and the United States. These gardens are designed to serve specific needs in their local communities and are often managed by those same communities. In recent years, the trend has been for botanic gardens to gain greater financial and administrative independence, often becoming trust administered and operating partly with funds gained through independent fund raising efforts.

Botanic gardens worldwide have been classified into 12 major types (Wyse Jackson and Sutherland, 2000, p. 14). Many botanic gardens have multipurpose roles and consequently, do not fit neatly into any well-defined category.

1. 'Classic' multipurpose gardens – these are often institutions with a broad range of activities in horticulture and horticultural training; research, particularly in taxonomy with associated herbaria and laboratories; and public education and amenity. They are generally state supported.
2. Ornamental gardens – these are often very beautiful establishments with diverse plant collections that are documented; they may or may not currently have research, education, or conservation roles. Some ornamental gardens are privately owned and many municipal gardens fall into this category.
3. Historical gardens – these include the earliest gardens developed for the teaching of medicine; some were established for religious purposes. A number of these gardens are still active in medicinal plant conservation and research, and today are primarily concerned with the collection and cultivation of medicinal plants and increasing public awareness about them.

4. Conservation gardens – most of these have recently been developed in response to local needs for plant conservation. Some contain, or have associated areas of, natural vegetation in addition to their cultivated collections. Included in this category are native plant gardens, which only cultivate plants from their surrounding region or national flora. Most conservation gardens play a role in public education.
5. University gardens – many universities maintain botanic gardens for teaching and research and many of these gardens are open to the public.
6. Combined botanical and zoological gardens – these are currently reassessing the roles of their botanical collections. Plants collections are being researched and developed that provide habitats for the displayed fauna, and interpretation of these habitats to the general public is an important element.
7. Agro-botanical and germplasm gardens – they function as an *ex situ* collection of plants of economic value or potential for conservation, research, plant breeding, and agriculture. Several are experimental stations associated with agricultural or forestry institutes and contain associated laboratory, plant breeding, and seed testing facilities, but many are not open to the public.
8. Alpine or mountain gardens – these are most frequently in mountain regions of Europe and some tropical countries. They are specifically designed for the cultivation of mountain and alpine flora, or in the case of tropical countries, for the cultivation of subtropical or temperate flora. Some alpine and mountain gardens are satellite gardens of larger lowland botanic gardens.
9. Natural or wild gardens – these contain an area of natural or seminatural vegetation, which is protected and managed. Most are established to play conservation and public education roles and include areas where native plants are grown.
10. Horticultural gardens – these are often owned and maintained by horticultural societies and open to the public. They exist primarily to foster the development of horticulture through the training of professional gardeners, plant breeding, registration, and conservation of garden plant varieties.
11. Thematic gardens – these specialize in growing a limited range of related or morphologically similar plants, or plants grown to illustrate a particular theme generally in support of education, science, conservation, and public display. These include orchid, rose, *Rhododendron*, bamboo and succulent gardens, or gardens established on such themes as ethnobotany, medicine, bonsai, topiary, butterfly gardens, carnivorous plants, and aquatics.
12. Community gardens – these are generally small gardens with limited resources, developed for and by a local community to fulfill its particular needs such as recreation, education, conservation, horticultural training, and the growth of medicinal, and other economic plants.

Distribution of Botanic Gardens

Worldwide there are 3026 known botanic gardens, in 175 countries or territories (Appendix 1). The most comprehensive

overview of the distribution and occurrence of botanic gardens is provided by the on-line 'Garden Search' database developed by Botanic Gardens Conservation International (www.bgci.org).

Earlier efforts to document the number, distribution, facilities, and activities of botanic gardens were represented by a series of International Directories of Botanical Gardens (i.e., Howard *et al.*, 1963; Henderson and Prentice, 1977; Henderson, 1983; Heywood *et al.*, 1990). A review of these directories highlights a remarkable increase in the number of botanic gardens. In the 1983 edition, 798 botanic garden entries were recorded. The 1990 edition recorded more than 1400 botanic gardens and arboreta and since that directory was published, the number of botanic gardens and arboreta known worldwide has more than doubled to a total of 3026 in a period of around 20 years. This represents a large number of newly established botanic gardens, as well as the revitalization and transformation of existing plant collections, parks, and other gardens into botanic gardens. BGCI's 'Garden Search' database was originally developed based on the earlier 1990 Directory and now as an on-line resource it enables individual botanic gardens to maintain and contribute data and information about their own institutions. Data on the number and distribution of botanic gardens worldwide presented in this article draws heavily on this database.

While the number of known botanic gardens worldwide has increased rapidly over the past decades, it is recognized that more than 50% of the world's botanic gardens have been created within the past 50 years. Of those for which the date of their foundation is known, only about 750 were established before 1950. The current trend for the creation of new botanic gardens in many parts of the world shows no signs of diminishing and each year many new botanic garden institutions are being proposed, planned, constructed, or opened.

Approximately one quarter of the known botanic gardens of the world occur in Europe (823 – 24%) with the largest numbers in the United Kingdom (117), France (104), and Germany (104) (Table 1). A similar number occur in North America (836 – 24%), in the United States (733), and Canada (103). In other regions of the world large numbers of botanic gardens occur in China (148), Australia (132), India (131), and the Russian Federation (109). Of all the regions of the world, the Middle East has the least number of botanic gardens (28), but there are also relatively few in South East Asia (49) and the Caribbean Islands (54) (Table 1). In Latin America (South and Central America and parts of the Caribbean), there has been a rapid rise in the number of botanic gardens in many countries in recent decades, for example, in Mexico (95), Argentina (48), Brazil (40), and Colombia (28). In the Caribbean, Cuba has 12 botanic gardens and in Africa, the largest number of botanic gardens is found in South Africa (22) and Nigeria (16) (Figure 1, Table 1, Appendix 2, Box 1).

There are less than 50 countries and territories without any botanic gardens (Table 2). Of these, about 40% are in Africa or the Middle East. There are also relatively few well-established botanic gardens in the countries and territories that make up the Pacific islands with only New Zealand having a significant number (20).

Table 1 Distribution and number of botanic gardens

Region	Number of botanic gardens
Africa and the Indian Ocean	157
East and South and South-west Asia	432 ^a
Australasia	164 ^b
Caribbean Islands	54
Central America	117 ^c
Europe	823 ^d
Former Soviet Union	193 ^e
Middle East	28
North America	836 ^f
South America	173
Southeast Asia	49
Total	3026

^aExcludes South-East Asia.

^bIncludes the southern pacific islands and Papua New Guinea.

^cIncludes Mexico.

^dIncludes the Baltic countries that were part of the former Soviet Union (but not Belarus, the Russian Federation and Ukraine) and Greenland.

^eExcludes Estonia, Latvia and Lithuania.

^fCanada and the USA only.

Early History of Botanic Gardens

No one can doubt the remarkable contributions that botanic gardens have made to the development of human societies and culture over the past few centuries. We know, for example, that they became an important expression of the rebirth of Europe in the Renaissance, particularly with the establishment of a series of early botanic gardens in Italy and other European countries in the sixteenth century (Prest, 1988). These botanic gardens, regarded as the first in the world, were established as university physic gardens, whose primary function was to cultivate 'simples' for medicines and teach medical botany to physicians and apothecaries (Schiebinger, 2004, pp. 57–58). The earliest was the Pisa Botanic Garden, founded in 1543 by Luca Ghini, and followed closely by the Padua Botanic Garden in 1545. The remarkable botanic garden of Padua survives today more or less in its original form. Its heritage values were recognized by UNESCO in 1997 and it was the first botanic garden to be added to the World Heritage list for its 'out-standing universal value.' In 2003, the Royal Botanic Gardens Kew in the UK was also listed as a World Heritage Site.

Many other early European botanic gardens survive today as cherished historic monuments, important sources of pride for their founding universities and cities. These include those in Zurich (1560), Leiden (1577), Leipzig (1579), Paris (1597), Montpellier (1598), Oxford (1621), Uppsala (1655), Edinburgh (1670), Berlin (1679), and Amsterdam (1682).

In other parts of the world, earlier gardens that could claim to be botanic were created in previous civilizations, such as China, pre-Hispanic Mexico, and the Arab world. In China, for example, the Du-Le Garden flourished during the Son dynasty (AD 420–479). Within this garden, a collection of medicinal plants was cultivated, each one displayed with its own label. However, we know too little on how these early gardens functioned to be sure whether any can be classified as true botanic gardens, according to BGCI's accepted definition.

Figure 1 Distribution and number of botanic gardens. Source: BGCI database (2012), www.bgci.org.

Box 1 Case study: botanic gardens in Brazil

The development of botanic gardens in Brazil illustrates the remarkable recent growth of botanic gardens. Brazil is rich in plant species and, nationally, can be regarded as one of the world's most diverse countries for its biodiversity. Current estimates suggest that Brazil may contain in the region of 55,000 plant species, making the development of a strong base of botanic gardens an urgent priority to help manage and conserve such a rich heritage and diversity of plants. The Rio de Janeiro Botanic Gardens, founded in 1808, remains the largest, oldest and best supported botanical institution in that country. Indeed, it was the first botanic garden created in South America and is today the leading botanical institution in the continent. The second botanic garden founded in Brazil later that century was the Museu Paraense Emílio Goeldi e Parque Zoológico in Belem, in the State of Pará. The third major botanic garden established in Brazil was the Jardim Botânico de São Paulo, created in 1938. In the latter part of the twentieth century a remarkable explosion in the number of botanic gardens took place in Brazil. In the *International Directory of Botanical Gardens II* (1969) four botanic gardens were listed. In a subsequent *International Directory* published in 1990 (Heywood, Heywood and Wyse Jackson, 1990), the number of botanic gardens in Brazil had grown to 11. By 2000, the number had grown to include 26 institutions; three of those listed in 1990 are no longer mentioned (Bruni *et al.*, 2000). In a review of the world's botanic gardens prepared in 2001 (Wyse Jackson, 2001), the number listed had grown to 29 and today, the BGCI on-line 'Garden Search' database of botanic gardens of the world lists 40 institutions.

Table 2 Countries and territories without botanic gardens

Afghanistan	Liechtenstein
American Samoa	Maldives
Andorra	Mali
Aruba	Marshall Islands
Bahrain	Mauritania
British Indian Ocean Territory	Mayotte
Brunei Darussalam	Micronesia
Cambodia	Nauru
Central African Republic	New Caledonia
Chad	Niger
Cocos (Keeling) Islands	Niue
Comoros	Pitcairn
Cook Islands	Qatar
Cyprus	Saint Pierre and Miquelon
Djibouti	San Marino
Equatorial Guinea	Sao Tome and Principe
Eritrea	Somalia
Falkland Islands (Islas Malvinas)	Swaziland
French Polynesia	Syria
Guam	Timor-Leste (East Timor)
Guinea	Tonga
Guinea-Bissau	Tuvalu
Holy See (Vatican City)	Western Sahara
Kiribati	Yemen
Lebanon	

NB: Refer to Appendix 2 for a comprehensive list of countries with botanic gardens.

From these early beginnings, the major European botanic gardens have evolved to become the great institutions they are today, not only combining diverse activities in science and horticulture with public amenity and education, but also caring for a rich heritage of historic buildings, landscapes, living plants, and preserved collections. When considering the heritage importance of botanic gardens, their great buildings immediately come to mind such as the great glasshouses, their orangeries, statuary, fountains, terraces, and

pergolas. Wonderful historic buildings that survive today in European botanic gardens include Kew Palace (1631) at the Royal Botanic Gardens Kew, UK; the Curvilinear Glasshouse designed by Richard Turner (1843–1869) at the National Botanic Gardens, Glasnevin, in Dublin, Ireland; the Orangery of the University of Vienna Botanic Garden (1755), the eighteenth century King's Gate by Sabatini and the Villanueva Pavilion at the Royal Botanic Garden Madrid; and the Palm

House (1872–1874) of the University of Copenhagen Botanic Garden. Nevertheless, our botanic garden heritage is much more than this. The collections of living plants, herbaria, libraries, seed banks, and works of art, manuscript archives, and other preserved collections contain tens of millions of specimens, representing an unequalled library of life and a window to the plant kingdom. Botanic garden herbaria alone contain almost 150 million preserved plant specimens, collections on which the scientific names and descriptions of most plant species have been based. Together botanic gardens grow representatives of about 100,000 plant species – perhaps a quarter of the world's plants, represented by some 6 million individual plant holdings.

In temperate regions a large number of urban municipal botanic gardens were founded in the nineteenth and twentieth centuries. In the twentieth century, such gardens were a particular feature in the United States, Australia, and New Zealand. Many of these gardens did not develop major scientific facilities, but there are notable exceptions to this, such as Missouri Botanical Garden, which was founded in 1859, the first botanic garden in the United States. Another exception was the Palmengarten in Frankfurt, Germany, founded in 1869. Most of these municipal botanic gardens developed significant activities in horticulture, building and maintaining major documented plant collections, as well as community engagement for recreation and informal learning.

In the countries of the former Soviet Union, the earliest botanic gardens are in Russia. The Apothecaries Garden of Moscow State University was created in 1706 and the botanic gardens of the Komarov Institute in St Petersburg were founded in 1713. Nevertheless, many of the 100+ botanic gardens in this region have been created within the past 50 years, mainly to act as centers for botanical research and plant introduction. They are generally associated with their national academy of science and universities. In China, more than 100 botanic gardens have been created in the past 20 years to support horticulture, research, native plant conservation, local education, and as a place for public relaxation.

The contribution of botanic gardens to the exploration of so many parts of the world is often underestimated. The interests of naturalists and explorers such as David Douglas, Augustine Henry, Joseph Banks, Archibald Menzies, and many more were stimulated and fostered by their connections with botanic gardens, helping to discover and introduce exotic plants from many parts of the world that have become a fundamental part of our familiar garden floras.

The world's botanic gardens have played a fundamental part in developing present day trade and economies of many countries and also helped shape patterns of agriculture in many parts of the world (Box 2).

The earliest tropical botanic gardens were motivated by considerations of trade and commerce, rather than by science for its own sake. European colonial powers, particularly Britain, the Netherlands, and to a lesser extent Germany, Belgium, Spain, and Portugal, established important tropical botanic gardens in their colonies in Africa, the Caribbean, India, South-East Asia, and South America in the eighteenth and nineteenth centuries. These tropical colonial botanic gardens became icons of modernity and had three main purposes. First, they were a place to study plants and their uses locally to support the new

Box 2 Case study: the contribution of botanic gardens to development

During 1560–1620, the horticultural explosion of botanic garden development is principally as a result of globalization which earlier work by Stafleu (1969, p. 35–36) attributed to the growth to the close political and economic relations between Turkey and Austria, which resulted in the introduction of flowers into Western Europe. As part of this globalization process, the flourishing trade and economy of The Netherlands, Austria and Germany saw the centre of horticultural activity shift from Italy at the end of this period (Stafleu, 1969, p. 38) and botanical institutions began to influence trade, economies and consequently, development. Arguably, this influence is still felt to the present day and the tulip industry is a good case in point. Carolus Clusius, the first director of the botanic garden at Leiden in The Netherlands, played a pivotal role in the history of its cultivation and was responsible for distributing many new varieties of bulbs throughout Europe (Pavord, 2000, p. 57–58). His work transformed the gardens of northern Europe (Pavord, 2000, pp. 57–58) and the legacy of his work is its contribution of the horticultural sector to the Dutch economy. Today, Dutch producers account for 93% of the total EU export of flower bulbs (Netherlands Turkey Trade Directory, accessed 03/02/2012).

colonial settlements (Holtum, 1970, p. 707; Huxley, 1992, p. 376). Second, they were introduction centers for species that would be useful to the local economy (Huxley, 1992, p. 376). Third, some were created by governments as instruments of colonial expansion and commercial development (Heywood, 1987, p. 3). Consequently, the work within these tropical botanic gardens significantly influenced scientific, cultural (Huxley, 1992, p. 374), and economic development of many tropical countries by playing a major role in the establishment of agriculture (Heywood, 1987, p. 3; 1990, p. 4; Brockway, 2002), horticulture, forestry (Holtum, 1970, pp. 707–708, 710–711; Heywood, 1991; Given, 1993, p. 38) and trade routes (Hill, 1915, p. 210; Huxley, 1992, p. 376).

The first botanic garden to be founded in the tropics was the Pamplemousses Botanic Gardens in the Indian Ocean island of Mauritius, founded in 1729. It was initially established to provide fresh fruit and vegetables for the colony and to provide provisions for ships calling at the nearby port of St Louis. Through the Garden many economic plants were introduced, such as sugarcane and spice plants, which became the basis of the island's economy. Many economically useful plants were introduced through the earliest tropical botanic gardens, such as breadfruit, cinchona, cloves, cocoa, coffee, oil palm, and rubber, often associated with one of the major European gardens such as Amsterdam and Kew. Notable amongst these early tropical gardens are St Vincent (1765); Calcutta, India (1787); Rio de Janeiro, Brazil (1808); Sydney (1816) and Hobart (1818), Australia; Bogor, Indonesia (1817); Peradeniya, Sri Lanka (1821); Durban, South Africa (1849); Singapore (1859), as well as Bath (1779), Castleton (1859), Cinchona (1868), and Kingston (1872), all in Jamaica. Most of these early tropical botanic gardens still thrive today. The first oil palm (*Elaeis guineensis*), introduced into Indonesia in 1848 from tropical Africa, survived until approximately 20 years ago at the Bogor Botanic Garden (Kebun Raya Bogor) on the island of Java, the ancestor of the high-grade oil palms that are now widely cultivated in plantations in Indonesia and Malaysia.

Botanic Gardens and Research

Botanic gardens are extremely active worldwide in undertaking and promoting scientific research on plants and on biological diversity in general. Their collections and libraries provide important resources to support such research and many botanic gardens have excellent research facilities either within or associated with the institution. These include laboratories, herbaria, greenhouses, and growth chambers with controlled conditions, field experimental areas, climatic, and weather stations, data management systems, and advanced equipment for molecular, and genetic studies. Many botanic gardens are closely associated with universities and therefore, have special opportunities to undertake or develop research programs.

Plant taxonomy has traditionally been the primary focus of plant science research in many of the major botanic gardens, in particular those with major associated herbaria. This has resulted in the preparation of a number of major floristic and taxonomic works by such botanic gardens as the Royal Botanic Gardens Kew, Missouri Botanical Garden, New York Botanical Garden, and the Royal Botanic Garden Edinburgh (Box 3). Notable regional floras prepared either by, or with the close involvement of, botanic garden-based scientists include Floras of North America, China, the Arabian Peninsula, the Greater Antilles, Central America, Tropical East, and West Africa.

Box 3 Case study: developing a world flora on-line by 2020

Through decision X/17 of the Conference of the Parties of the U.N. Convention on Biological Diversity held in Nagoya, Japan in 2010, a consolidated update of the Global Strategy for Plant Conservation (GSPC) 2011–2020 was adopted. Target 1 of the Global Strategy for Plant Conservation calls for the achievement of 'An online Flora of all known plants' by 2020.

A widely accessible Flora of all known plant species is a fundamental requirement for plant conservation. The terms and technical rationale for Target 1, within the Global Strategy for Plant Conservation (GSPC) 2011–2020, propose that an online World Flora be developed as a framework capable of accommodating regional floristic information (at national or lower level) that can provide answers in both regional and global contexts. It is suggested that the Flora should include accepted names and a comprehensive synonymy, building on the results of the previous (2010) Target 1 aimed to develop 'a widely accessible working list of known plant species as a step towards a complete world flora' (Secretariat of the Convention on Biological Diversity, 2002, p.6). This target was achieved at the end of 2010, as The Plant List (www.theplantlist.org). The terms and technical rationale suggest that a World Flora should include geographic distributions to at least country level, drawing on national floras, checklists, and monographs; habitat data; identification tools (e.g., interactive keys, images, and descriptions); conservation status (with links to assessments being carried out under Target 2); and other enhancements as practicable, for example, vernacular names. Much of these data already exist in digital or printed format and can be used to populate the Flora.

When complete, the World Flora online will be expected to include information on approximately 400,000 plant species, and comprise vascular plants and bryophytes. Leadership in the development of the proposed World Flora is likely to be provided by the four largest botanic garden plant science institutions, i.e. Missouri Botanical Garden, New York Botanical Garden, Royal Botanic Garden Edinburgh, and the Royal Botanic Gardens, Kew.

The current main research areas in botanic gardens include:

- biotechnology
- climate change
- conservation biology
- conservation genetics
- data management systems & information technology
- ecology
- ecosystem conservation
- education
- ethnobotany
- exploration
- floristics
- horticulture
- invasive species biology and control
- molecular genetics
- phenology
- plant breeding
- plant population dynamics and diversity
- pollination biology
- propagation
- restoration ecology
- seed and spore biology
- species recovery
- systematics and taxonomy
- urban environments.

Not all botanic gardens have the resources (i.e., staff, facilities, and expertise) to enable them to play significant roles in botanical research. Nevertheless, most can contribute to such research by making their collections and facilities available to researchers.

Botanic Garden Collections

Over the past few decades there has been an increasing trend amongst botanic gardens to cultivate native plants from their own regions. Many botanic gardens have also assumed special responsibilities for the cultivation of rare and endangered plants and other taxa of conservation importance. In some cases, botanic gardens concentrate on the development of their collections following particular thematic, taxonomic and geographical lines, including the broad categories outlined below. It should be stressed, however, that this list is by no means complete and it should not be suggested that botanic gardens are either largely focused on such thematic collections, or that they do not maintain extensive collections of groups that fall outside of any of the categories listed.

The following broad categories are well represented worldwide in botanic garden *ex situ* collections:

Thematic collections

- Alpine and rock garden plants
- Aromatic plants
- Bonsai
- Bulbs and other geophytes
- Carnivorous plants
- Medicinal plants
- Ornamental plants (including cultivars and their wild progenitors)
- Rare and endangered plants

- Temperate fruits
- Temperate herbaceous perennials
- Temperate trees, shrubs, and climbers
- Tropical fruits (particularly fruit trees)
- Tropical timber trees
- Tropical flowering and other ornamental trees and shrubs
- Wild crop relatives
- Xerophytes

Taxonomic collections

- A wide range of temperate woody families (such as Aceraceae, Betulaceae, Fagaceae, Rosaceae).
- Aroids
- Bromeliads
- Cacti
- Conifers
- Crassulaceae
- Cycads
- Euphorbiaceae
- Ferns
- Ficus
- Grasses (including bamboos)
- Leguminosae
- Orchids
- Palms
- Rhododendrons

Geographical collections

- Native plants of temperate North America, Europe, Asia.
- Woody native plants of temperate Australia, New Zealand, and South America.
- Plants of Mediterranean regions of Europe, Southern Africa, South America, and Australia.
- Island plants, such as from Macaronesia, the Mascarene Islands, New Zealand, Japan, and Hawaii.
- Plants of the mountains of Europe, North America, and Asia.

Less well represented in botanic garden collections are the floras of tropical continental South America, South-east Asia and Africa, and other countries where there are still a limited range and number of botanic gardens (Appendix 2).

Botanic gardens *ex situ* (off-site) collections contain more than 6 million living plant accessions worldwide. The figures given in Table 3 represent a conservative estimate based on the numbers of species and/or accessions reported by botanic gardens and included in BGCI databases. For some institutions and countries, knowledge of their collections is so scanty as to make it impossible even to estimate the likely number of accessions in a country. In those cases, an assumption has been made that no collections are held and they were excluded from the calculations. For that reason, the final total of + 6 million accessions in botanic gardens worldwide must be regarded as extremely conservative estimate and it is suggested that a true figure may be as much as 20% to 50% higher.

As Table 3 shows, the distribution of accessions in botanic gardens worldwide is uneven. The majority of collections are in Europe and North America (making up more than 50% of the total). The collections in most tropical and developing countries are significantly smaller

Table 3 Botanic garden living plant accessions – estimated numbers and their distribution

North America	700,000
Russia and former Soviet Union countries	389,500
Africa and Indian Ocean Islands	216,600
Caribbean Islands	86,100
Western Europe	2,800,500
Central and Eastern Europe	404,000
Australasia and Oceania	331,500
South West Asia and the Middle East	58,500
South Asia	224,000
South America	145,500
Middle America	138,700
East and South East Asia	636,000
Total	6,130,900

than those in many temperate countries. This is not only partly due to an imbalance of institutional resources between such regions, but also due to the fact that many of the botanic gardens in tropical and developing countries are younger institutions without the long history of development of many European countries, that has allowed the growth of extensive collections built up over decades, and sometimes centuries.

Botanic Garden Herbaria

A high percentage of the botanic gardens of the world contain, include or are closely associated with herbaria. The largest herbaria are generally found in the oldest and largest botanical institutions in each country and region. Many contain diverse, historic and irreplaceable scientific resources documenting the world's plant diversity. For historic reasons, many original collections and much type material on which plant names have been based are housed in herbaria outside the natural range of the species concerned. To facilitate scientific research, most herbaria have a policy to provide free access to their collections to bonafide users for the purposes of scientific study. Although the majority of specimens preserved in botanic garden herbaria are of vascular plants, some important collections of nonvascular plants (e.g., bryophytes), algae and fungi are also maintained. The combined total number of specimens in botanic garden herbaria worldwide exceeds 150 million.

Major botanic garden herbaria include:

- Museum National d'Histoire Naturelle, Paris, France (8,000,000 specimens);
- New York Botanical Garden, USA (7,300,000 specimens);
- Komarov Botanical Institute and Botanic Garden, St Petersburg, Russia (7,160,000 specimens);
- The Royal Botanic Gardens Kew, UK (7,000,000 specimens);
- Missouri Botanical Garden, St Louis, USA (6,300,000 specimens)
- Conservatoire et Jardin Botaniques, Geneva, Switzerland (6,000,000 specimens);
- The Berlin Dahlem Botanic Garden (3,500,000 specimens);

- National Botanic Garden of Belgium (3,200,000 specimens);
- University of Helsinki Botanic Garden, Finland (3,126,000 specimens);
- Uppsala University Botanic Garden, Sweden (3,100,000 specimens);
- Royal Botanic Garden Edinburgh, UK (3,000,000 specimens);
- Jena University Botanic Garden, Germany (3,000,000 specimens);
- Copenhagen University Botanic Garden, Denmark (2,510,000 specimens);
- Beijing Botanic Garden, China (2,469,596 specimens);
- Kebun Raya Bogor, Indonesia (2,000,000 specimens);
- University of Oslo Botanic Garden, Norway (1,800,000 specimens);
- University of Tokyo Botanic Garden, Japan (1,700,000 specimens);
- Goteborg Botanic Garden, Sweden (1,600,000 specimens);
- Indian Botanic Garden, Kolkata (Calcutta), India (1,500,000 specimens);
- Botanischer Garten der Universitat Wien, Vienna, Austria (1,400,000 specimens);
- Australian National Herbarium, Australia (1,400,000 specimens);
- Pretoria National Botanical Garden, South Africa (1,200,000 specimens);
- Royal Botanic Gardens Melbourne, Australia (1,200,000 specimens);
- Real Jardin Botanico, Madrid, Spain (1,100,000 specimens);
- Royal Botanic Gardens Sydney, Australia (1,000,000 specimens);

Botanic Garden Education

The Convention on Biological Diversity (CBD) (United Nations Environment Programme, 1994) and Agenda 21 (United Nations, 1993), resulting from the Earth Summit held in Rio de Janeiro in 1992, highlighted the importance that public education and awareness raising play in promoting sustainable development, and improving the capacity of people to address environment and development issues.

The importance of botanic gardens in public education and raising awareness about the environment and sustainable development has grown in recent years. Some botanic gardens have sought to incorporate a vision for a more socially and environmentally sustainable future into their educational programming (see Dodd and Jones, 2010). As botanic gardens worldwide collectively receive in excess of 250 million visitors a year, they have considerable potential and opportunities to reach huge audiences with their educational programs. With growing urbanization, botanic gardens play an ever increasing and crucial role in public education, awareness raising, and engaging people with nature. In some cities they may represent one of the only opportunities for urban inhabitants to visit a natural or seminatural setting in

their region. As the population becomes isolated from the natural environment there is a risk that people will become unaware of how their daily lives impact on the environment (Dodd and Jones, 2010). Therefore, there is a need to increase public sensitivity to environment and development problems, and foster a greater sense of personal environmental responsibility, motivation, and commitment towards sustainability.

A role of botanic gardens in education is also to act as an advocate for the maintenance of biodiversity and so educational topics addressed by botanic gardens include, but are not limited to, development issues, invasive threats, genetically modified foods, the relationship between people and plants, the role of science in plant conservation, sustainable living, and the value of biodiversity.

Formal education is a major focus for many botanic gardens and has strong historical roots, especially for such university botanic gardens as Oxford and Cambridge in the UK. The education role can involve providing materials and expertise for university teaching, as well as devising and providing formal education programs for other age groups. This often involves working with schools and contributing to schools' curricula.

Increasing more informal learning activities are being offered by botanic gardens. These are most often directed toward particular target audiences such as families, casual visitors, young people, and decision makers. Botanic gardens use a variety of techniques to encourage learning, engage a diverse community, and convey educational messages including guided tours, audio tours using latest technologies, social media, classes and workshops, exhibitions, festivals, interpretive signs, publications, and other such media as the internet, radio, television, and newspapers.

Botanic Garden Networks and Their Development

The International Association of Botanic Gardens (IABG)

The development of botanic garden networks began in the 1950s with the establishment of the International Association of Botanic Gardens (IABG) in 1954; although strong links between individual botanic gardens around the world have existed for more than a century. Such links were generally for the exchange of plant material and expertise. The International Association of Botanic Gardens (IABG) is affiliated to the International Union of Biological Sciences (IUBS) as a commission of the International Association of Botanical and Mycological Societies (IABMS). In recent years, IABG has not been active and the role in facilitating networking has been played by other international organizations, in particular Botanic Gardens Conservation International, as well as national and/or regional botanic garden network organizations.

The IABG operated by means of a series of geographically based regional divisions – in Europe, Ibero-Macaronesia, Latin America, Australasia-Oceania, east Asia, and with what was then the American Association of Botanic Gardens and Arboreta (now the American Public Garden Association) providing a corresponding service to institutions in North

America. All botanic gardens, arboreta, or other institutes and their staff were eligible for membership of IABG through the various regional divisions.

The aims of IABG are to promote:

- international cooperation between botanic gardens, arboreta, and similar institutes maintaining scientific collections of living plants;
- the study of taxonomy of plants to benefit the world community;
- documentation and exchange of information, living plants, and specimens between botanic gardens and similar institutes;
- the conservation of plants through cultivation and other means within botanic gardens and similar institutes;
- the introduction to cultivation of appropriate plants of benefit to the community;
- habitat conservation by cooperation between IABG and other relevant bodies;
- horticulture as an art and science.

Botanic Gardens Conservation International

Botanic Gardens Conservation International (BGCI) is a membership organization and the largest international network for botanic gardens. Its focus is primarily on the conservation of plant diversity, highlighting not only the importance of biodiversity conservation, but also the essential links to global issues including poverty, human well-being and climate change. It includes more than 700 members, which are mostly botanic gardens from 118 countries and the organization aims to support and empower its members, as well as the wider conservation community, so that their knowledge and expertise can be applied to reversing the threat of the extinction crisis facing plants.

BGCI was first established in 1987 as the IUCN Botanic Gardens Conservation Secretariat (BGCS). It began to build its membership of botanic gardens worldwide and develop a program of activities in support of botanic gardens. In 1989, *The Botanic Gardens Conservation Strategy* was published and the following year BGCS became independent from IUCN, and subsequently known as Botanic Gardens Conservation International (BGCI). BGCI registered as a UK charity and independence helped it to gain a greater measure of self-determination and made it possible for the organization to receive charitable donations in the UK. In addition to its head office in the UK, BGCI has national foundations in the USA and Russia and regional offices in several countries (www.bgci.org).

A primary concern of BGCI has been to provide a means for botanic gardens in all parts of the globe to share information and news about their activities, programs, and any new advances made that benefit conservation and education. Networking and capacity building for botanic gardens has been assisted through BGCI's magazines and the publication of a series of resource books, manuals, and policy handbooks on the development of botanic gardens and their roles, on such subjects as plant reintroductions, *ex situ* conservation, environmental education, education for sustainability, computer software, regional action plans, the Convention of Trade

in Endangered Species of Fauna and Flora (CITES) and the Convention on Biological Diversity (CBD). Furthermore, it has supported its members by providing a number of tailor-made training and capacity-building workshops and works collaboratively with the Royal Botanic Gardens Kew to offer several International Diploma courses specific to the key roles of botanic gardens.

BGCI also organizes an international botanic gardens congress every 3 years since the first such congress in Las Palmas de Gran Canaria, Spain in 1985. BGCI also holds regular international congresses focusing on botanic gardens education.

BGCI has developed unique on-line computer databases on the botanic gardens of the world. The 'Garden Search' lists every known botanic garden, arboretum and many more similar institutions maintaining living plant collections in cultivation, with details of the facilities, collections, and work of more than 1800 botanic gardens. The 'Plant Search' lists details of collections in botanic gardens worldwide including locating rare and threatened plant species in cultivation around the world.

This database is compiled from the lists of living collections submitted to BGCI by the world's botanic gardens. The database presently includes more than 575,000 records. Information on threat status of each taxon is provided by a direct link to IUCN's 1997 and latest Red Lists. Further nomenclatural and bibliographic information is provided through the link to the TROPICOS database maintained by the Missouri Botanical Garden. The database is also linked to lists of medicinal plants, crop wild relatives and CITES listed plants. The 'Plant Search' database is recognized as an important mechanism to monitor the achievement of the *ex situ* plant conservation target of the Convention on Biological Diversity's Global Strategy for Plant Conservation (GSPC).

National and Regional Botanic Garden Networks

The past decade has also seen the establishment and growth of a wide range of national and regional organizations in all parts of the world for, or including, botanic gardens. National networks of botanic gardens help gardens work together to share information and coordinate a united role in the country. Partnerships and networking with bodies that have a complementary mission increase support for conservation initiatives. There are well-established networks in several countries including Australia, China, India, Mexico, Russia, South Africa, and the United States (refer to www.bgci.org). Furthermore, the networks in such regions as Europe, the Caribbean and sub-Saharan Africa, have had a significant role in strengthening capacity and extending conservation collaborations.

BGCI has worked to support this development and provide such organizations with assistance and support and, in addition, to collaborate closely with these sister networks. Amongst its activities in this area it provides a secretariat for the European Botanic Gardens Consortium, a body linking the national botanic garden networks in Europe.

In the United States, the Center for Plant Conservation is a network of botanic gardens that is focused primarily on

preventing the extinction of US native plants. The Center is a network of 37 botanic gardens. Founded in 1984, the Center coordinates a national program of *ex situ* conservation of rare plant material, with the aim of ensuring that material is available for restoration and recovery efforts for these species. CPC also works in research, restoration, technical assistance, education, and advocacy through the efforts of the network and its national office based in St Louis. The cooperative CPC network maintains the National Collection of Endangered Plants of more than 750 of native plants. Live plant material is collected from nature under controlled conditions and then maintained as seed, rooted cuttings, or mature plants.

Botanic Gardens and Plant Conservation

Throughout the world, the loss of biodiversity is recognized as one of the most challenging issues that we face if a sustainable planet is to be achieved in the future and if we are to safeguard the genetic resources that will be required by future generations. Despite the adoption by most of the world's countries of national biodiversity conservation strategies and plans during the past decade, biodiversity continues to rapidly disappear as natural habitats are destroyed and more and more species become endangered. Worldwide it is recognized that tens of thousands of plant species are rare or endangered and potentially face extinction in this century if current trends continue. Although the potential extinction crisis faced by plants worldwide has been recognized for several decades, only recently has a coherent plan of action for their conservation been proposed.

Ex situ facilities, such as botanic gardens, have shown an ability and vital role in managing plant resources and the evolution of their conservation role has reflected a scientific and cultural shift for plant collections from having a curatorial goal, which focuses on accumulating typological specimens, to the adoption of population genetics as a working tool to conserve threatened species (Maunder *et al.*, 2004a, p. 7 and b, p. 413).

The Botanic Gardens Conservation Strategy states that 'The purpose of *ex situ* conservation is to provide protective custody. It is justifiable only as part of an overall conservation strategy to ensure that species ultimately survive in the wild. Its role should be seen as a means to an end, not an end in itself: as a source of material for reintroduction into damaged habitats and to enhance populations as part of ecosystem management, for research and education, for selecting material for introduction into the nursery trade, local agriculture, amenity planting, and local forestry, etc. Another role is to take the pressure off wild populations for plants that are likely to be the subject of interest by scientists, commercial horticulturists, hobbyists, or local gatherers. Above all, *ex situ* conservation makes plants available for use by [humankind] (IUCN-BGCS and WWF, 1989, p. 21)'.

Ex situ conservation of wild plants has become a central and unique role of botanic gardens and has several purposes (Box 4). They have the appropriate facilities and staff expertise in botany and horticulture to be effective centers for *ex situ* conservation. *Ex situ* conservation can include the

Box 4 The purposes of *ex situ* conservation

Ex situ conservation has several purposes:

- Rescue threatened germplasm.
- Produce material for reintroduction, translocation, reinforcement, habitat, and landscape restoration and management.
- Produce material for conservation biology research.
- Bulk up germplasm for storage in various forms of *ex situ* facility.
- Supply material for various purposes to remove or reduce pressure from wild collecting.
- Grow those species with recalcitrant seeds that cannot be maintained in a seed store.
- Generate skills and knowledge to support wider conservation aims.
- Make available material for conservation education and display.

Source: Reproduced from Smith P (2006) Wild seed bank and taxonomy. In: Leadley E and Jury S (eds.) *Taxonomy and Plant Conservation*, pp. 294–304. UK: Cambridge University Press.

maintenance of samples of whole individuals, as well as seed, pollen, vegetative propagules, and tissue or cell cultures.

Ex situ plant conservation activities do not themselves constitute the protection of wild species; they in fact complement the wider range of plant conservation-related activities (Smith, 2006). However, caution is needed because as a method of conservation, *ex situ* is inherently deficient in that it is not usually possible to maintain more than a limited sample of the genetic diversity in cultivation or in storage. Prance (2004, p xiii) highlights that a drawback to *ex situ* conservation is that '...in most cases it halts or distorts the natural process of evolution.' Consequently, it is often regarded as preservation rather than conservation. In addition, it may lead to unpredictable genetic change and can become in practice a form of domestication. In contrast, *in situ* conservation, at least in theory, allows plant populations to develop and evolve in, and as part of, the ecosystem of their natural habitat. In practice, both methods should form an integrated conservation response for the retention and restoration of wild plant diversity (Maunder *et al.*, 2004, p. 5).

Increasingly an important type of botanic garden is developing, particularly in some tropical countries, where gardens have been created alongside national parks and play key roles in integrated conservation, sustainable development, and public education. Examples of these botanic gardens include Limbe Botanic Garden in Cameroon and the Tam Dao and Cuc Phuong Botanic Gardens in Vietnam.

Despite the above mentioned issues, *ex situ* conservation in botanic gardens has several important benefits:

- *Ex situ* conservation may be the only option available when a natural habitat has been destroyed.
- It can be very cost-effective.
- Seeds of many species especially lend themselves to compact storage (allowing bulk samples); they are economical and can undergo long-term storage.
- Plant collections can give users ready access to a wide range of genetic variation within a species.
- Botanic gardens provide propagation and often research facilities, together with horticultural and other applied scientific skills needed in practical species conservation.

Box 5 Ex situ conservation priorities

Priorities identified for inclusion in *ex situ* plant conservation programs include the following:

- Species or taxa that are in immediate danger of extinction, either locally, nationally or globally.
- Species or taxa that are of local economic importance, such as minor food crops, medicinal plants and wild or cultivated plants providing the basis of local industries, agriculture, horticulture and crafts.
- Species or taxa, such as local ecotypes, that may be required for specific reintroduction or habitat restoration and management schemes.
- Local 'flagship' species or subspecies that will stimulate conservation awareness and can be incorporated into education and fund raising programs.
- Species or taxa that are of special scientific interest, such as narrow endemics or geographical relics.

Source: Reproduced from Wyse Jackson PS and Sutherland LA (2000) *The International Agenda for Botanic Gardens in Conservation*. UK: Botanic Gardens Conservation International.

- *Ex situ* conservation provides back-up for populations of threatened plants in the wild, contributing material for reintroduction, restocking, and restoration, as well as advice, and data for field management.

In 2002, the Global Strategy for Plant Conservation was agreed by the international community through the UN's Convention on Biological Diversity to address the potential loss of so much of the world's plant diversity (Secretariat of the Convention on Biological Diversity, 2002). To date, most global investment in *ex situ* conservation has focused on the retention of plant material of value for crop breeding (Maunder *et al.*, 2004b, p. 389). Although it is recognized that the conservation of plant resources is fundamental to the future survival of humanity and of many other species that rely on plants to provide the fabric of most terrestrial ecosystems, plant conservation beyond crops has barely received the attention that it needs until recent years (Box 5).

The role and value of *ex situ* conservation has increasingly been acknowledged in international conventions and legislation. Hand in hand with this development the botanic garden community has developed a series of international and national policies in relation to their priorities and activities in plant conservation. These include botanic garden action plans, contributions to national plant conservation strategies and individual botanic garden conservation policies and other documents.

At the international level several important botanic garden-focused policy documents have been prepared, primarily under the leadership and initiative of Botanic Gardens Conservation International. The most widely known such initiative is the International Agenda for Botanic Gardens in Conservation (Wyse Jackson and Sutherland, 2000), which is described below. It is currently being revised and updated by BGCI.

International Agenda for Botanic Gardens in Conservation

In 2000, Botanic Gardens Conservation International (BGCI) prepared and published the *International Agenda for Botanic*

Gardens in Conservation to provide a global framework for botanic garden policies, programs, and priorities in biodiversity conservation (Wyse Jackson and Sutherland, 2000). The key purpose was to assist botanic gardens worldwide to set their own future agendas to address the changes that are impacting on the world and to help guide their future responses to the environmental crisis. The agenda was based on contributions from and consultations with more than 300 institutions and individuals throughout the international botanic garden, botanical, and conservation communities.

The International Agenda defines the global mission of botanic gardens worldwide in conservation as:

- Stemming the loss of plant species and their genetic diversity worldwide.
- Focusing on preventing further degradation of the world's natural environment.
- Raising public understanding of the value of plant diversity and the threats it faces.
- Implementing practical action for the benefit and improvement of the world's natural environment.
- Promoting and ensuring the sustainable use of the world's natural resources for present and future generations.

A registration system for botanic gardens was subsequently launched and botanic gardens were invited to adopt the International Agenda as their (or part of their) institutional policy on conservation. Five hundred botanic gardens worldwide registered their contributions to the achievement of the International Agenda by making a written undertaking to work for the implementation of its provisions.

The *International Agenda for Botanic Gardens* has also been formally recognized by the international community and specifically by the United Nations Convention on Biological Diversity, which noted that it represents an important component of and contribution to the achievement of the Convention's Global Strategy for Plant Conservation (Secretariat for the Convention on Biological Diversity, 2002).

Global Strategy for Plant Conservation

For botanic gardens, the adoption of the Global Strategy for Plant Conservation (GSPC) by the Convention on Biological Diversity in April 2002 was both a significant landmark, and a major achievement. Botanic gardens were central to the development and subsequently to the implementation of this strategy (Wyse Jackson, 2002). It clearly demonstrated the value of botanic gardens immersing themselves in the political world of biodiversity policy making and advocacy.

The adoption of the Global Strategy for Plant Conservation in 2002, therefore, presented significant new opportunities and challenges for the botanical community throughout the world. The Strategy was developed in response to a growing realization that up to 100,000 plant species are currently threatened worldwide and new concerted action to promote programs focused on plants is urgently needed if huge losses in plant diversity are to be averted (Box 6).

The first phase of the GSPC (2002–2010) included a series of 16 outcome-orientated targets that proposed what needed to be achieved for plant conservation by 2010 (Secretariat of

Box 6 Global strategy for plant conservation

The ultimate and long-term objective of the Global Strategy for Plant Conservation is to halt the current and continuing loss of plant diversity. The strategy provides a framework to facilitate harmony between existing initiatives aimed at plant conservation, to identify gaps where new initiatives are required, and to promote mobilization of the necessary resources. It also provides a tool to enhance ecosystem conservation and the sustainable use of biodiversity and to focus on the vital role of plants in the structure and functioning of ecological systems and assure the continued and future provision of the goods and services such systems provide.

The scope of the strategy is:

- Understanding and documenting plant diversity
- Conserving plant diversity
- Using plant diversity sustainably
- Promoting education & awareness about plant diversity
- Capacity building for plant diversity

the Convention on Biological Diversity, 2002). The GSPC also provided a new and innovative framework against which government programs and the initiatives undertaken by a wide range of national and international organizations could be aligned. Through the adoption of the GSPC, governments throughout the world committed themselves to the implementation of the GSPC and to the achievement of the 16 international targets. In 2009, a comprehensive report on its achievements and progress towards the targets made was published (Secretariat of the Convention on Biological Diversity, 2009). Although the first phase of the GSPC (2002–2010) had almost come to an end, an updated Strategy for the period 2010–2020 was adopted. This strategy includes revised targets and renewed objectives, with the aim not only of moving forward the international plant conservation agenda with continued urgency, but also integrating such efforts with the CBD's Strategic Plan for Biodiversity 2011–2020 (Secretariat of the Convention on Biological Diversity, 2010). Both these strategies were adopted during the CBD's Conference of the Parties meeting in Nagoya, Japan in November 2010. The updated Strategy also seeks to align plant conservation policies more effectively with each country's development agenda, helping to address the causes of decline of plant diversity and ensure that economics, sustainable development, and biodiversity can go hand in hand.

Botanic Garden Roles in Addressing Climate Change

The achievement of plant conservation targets becomes even more challenging due to climate change. There are still few scientific assessments made on the impact of climate change on plant diversity and plant communities and there has to date been little incorporation of climate change mitigation and adaptation measures into National Biodiversity Strategies and Action Plans (particularly related to plants, plant-based ecosystems, and their conservation). Botanic gardens clearly have a responsibility and real opportunity to respond effectively to the climate change challenge. In Australia, for

example, the Council of Heads of Australian Botanic Gardens (CHABG) has developed and is implementing a national response from the country's capital city botanic gardens to climate change (CHABG, 2008).

At the risk of oversimplification, the key botanic garden roles in climate change can be broken down under five major headings:

1. Leadership, public awareness, education, and advocacy
2. Botanical and Ecological Research
3. *Ex situ* conservation of germplasm
4. *In situ* management of species and ecosystems, and the
5. Utilization of germplasm

Leadership, Public Awareness, Education, and Advocacy

Botanic gardens receive huge numbers of visitors annually (approximately 250 million) and have great opportunities to become centers of public awareness on the:

- realities and consequences of climate change
- importance of plants
- impact of climate change on plant diversity
- need to take immediate action
- contribution of botanic gardens to addressing climate change.

Botanical and Ecological Research

In botanical and ecological research related to climate change, many traditional and on-going botanic garden activities are highly relevant, such as plant taxonomy, exploration and monitoring of species and their ecosystems, status surveys and increasingly, the responses of plants and ecosystems to a changing environment.

The responses of plants to climate change are complex and in general, very poorly understood. These will be the drivers of plant extinction in the coming years and, if the loss of plants as a result of climate change is to be prevented, there will need to be greater knowledge of how individual plants and populations respond to the following factors, as well as the interactions between them:

- changed competition regimes
- changed seasonal temperatures and patterns
- changes in available water
- changed snow/frost/freezing regimes
- loss of pollinators
- inbreeding and population viability changes
- changed nutrient status of soils
- pests, diseases, and invasive species
- disturbance and ecological succession
- migrations
- food chains
- rising carbon dioxide (CO₂)
- tropospheric ozone (O₃)
- nitrogen cycle changes
- light levels
- methane (CH₄)

The broad fields of conservation biology and population genetics are of fundamental importance. They provide the basis for what we need to know in order to undertake species recovery, ecological restoration and increasingly the reconstruction or construction of new habitats and ecological units.

Research on invasive species and pathogens is an additional area where botanic gardens will be expected to contribute, using their diverse collections and knowledge to monitor and predict potentially damaging invasions and develop effective methodologies to manage, control, or eradicate them.

The importance of safeguarding and extending exists and new ecological corridors have often been stressed as a means to help mitigate the impact of climate change on biodiversity. In particular, these can assist the movement of pollinators and seed dispersers. For plants in most cases, however, the rates of climate change predicted will not provide sufficient time to migrate at a sufficiently rapid rate. In those cases assisted migration of species may become one of the only options available and botanic gardens will play a critical role in these activities.

Ex situ Conservation of Germplasm

The conservation of germplasm and the associated scientific research by botanic gardens is expected to represent a major component of their contribution to addressing the impacts of climate change on biodiversity.

Maintaining threatened plants in botanic gardens worldwide is already a significant component of their work, which is a well-recognized contribution towards the achievement of Target 8 of the Global Strategy for Plant Conservation. There may well be a case for formulating a long-term botanic garden action plan and target, say for 2050, to provide a basis for planning what capacity is needed for *ex situ* conservation through botanic gardens over the next 40 years.

The ongoing development of storage of seed through botanic garden seed banks will continue to form a major component of botanic garden contributions to *ex situ* conservation. Notable examples include the international efforts as part of the Millennium Seed Bank Partnership, an initiative of the Royal Botanic Gardens Kew, and the European ENSCONET project, as well as newly formed initiatives such as the Australian Seed Bank Partnership, which aim to safeguard Australia's flora through a national network of conservation seed banks.

In situ Management of Species and Ecosystems

Botanic gardens are also likely to be increasingly active in *in situ* management of species and ecosystems providing active interventions on species growing in the wild to try to reduce the worst impacts of climate change (e.g., clearance of invasive species and habitat enhancement).

In March 2011, leading botanic gardens came together to initiate the Ecological Restoration Alliance and use the combined wealth of their expertise, research knowledge, and unparalleled diversity of plant materials to restore degraded

ecosystems. The alliance is an initiative of BGCI working with these botanic gardens to develop and test good practice guidance at pilot sites around the world. This program will build on existing efforts of individual gardens, unite botanic gardens as a leading force in ecological restoration, and guide strategic action to restore threatened habitat around the world. The program aims to demonstrate that the essential components of successful restoration are the natural plant diversity of an area, the involvement of local people in the management and design of the program, and the acceptance of the impact of climate change (BGCI, 2011).

Utilization of Germplasm

The role of botanic garden in the utilization of germplasm is also likely to become increasingly important. This will be the case as new plants will be required for new situations, such as: breeding, development, and use of alternative economic plants, varieties and crops; supporting changing livelihoods (particularly in developing countries); and providing germplasm for ecological and restoration purposes. The importance of further developing collections of crop wild relatives in botanic gardens should be highlighted.

A key area where botanic gardens are increasingly playing a lead role is in the utilization of germplasm in species recovery and habitat restoration, including managing the migrations of species and the reestablishment of ecosystems in the face of climate change.

In outlining these five key areas for botanic garden involvement in climate change it should be noted that botanic garden research contributions will play a valuable cross-cutting role in all areas, including:

- understanding public attitudes to climate change and plants;
- the plant taxonomy that is required to underpin all botanical research;
- *in situ* and *ex situ* conservation methodologies and technologies;
- understanding the biology of species, ecosystems, and the goods and services they provide.

Botanic garden responses to biodiversity conservation, and in particular to climate change, will also involve fundamental changes in their horticultural practices and in the nature, composition and management of their living collections.

Botanic Gardens and the Sustainability Movement

Achieving environmental sustainability has become a major concern and challenge for governments and most major institutions worldwide as there is increasing awareness that the Earth's natural resources are finite and need to be used and managed with care and responsibility. It is recognized that sustainability has also become a matter of individual responsibility and one of the greatest personal challenges being faced by individuals is ensuring that our actions are not detrimental to the planet or threaten its environment or biodiversity. Botanic gardens, as leading environmental

organizations, face an even greater challenge not only to improve their own environmental performance, but also to ensure that the institutions are developed as models of sustainability.

It is clear that botanic gardens also need to provide leadership and guidance for those who still remain to be convinced of the urgency of the environmental crisis and the need to stem the loss of biodiversity. However, developing an individual botanic garden to become such a model is not an easy task. Most botanic gardens are very significant producers of carbon dioxide and reducing their carbon footprint requires innovation, determination, and sacrifices. In the temperate world most major botanic gardens have large expanses of heated glasshouses and very few are currently maintained by the use of renewable energy sources. Retrofitting botanic gardens to become modern energy-efficient institutions with a low environmental impact is a particularly difficult task, especially for those gardens that have inherited a diverse range of historic buildings, facilities, and glasshouses.

Nevertheless, despite the challenges we face it is clear that much can be achieved and constant improvements can be made to the ways in which we perform environmentally. To develop a more coherent response to the need to promote sustainability, some botanic gardens have developed and adopted a range of new policies and practices to guide their actions in this regard. The key components of such sustainability programs can be categorized under the following headings:

- Developing environmentally friendly practices in horticulture and botanic gardens management
- Promoting and supporting biodiversity conservation
- Supporting sustainable development locally, nationally, and internationally
- Education for and about the environment
- Recycling and reducing waste and energy consumption

Developing Environmentally Friendly Practices in Horticulture and Botanic Gardens Management

The key activities in relation to environmentally sustainable horticulture in botanic gardens include composting programs, the reduction, and eventual elimination of the use of peat from nonrenewable sources, elimination of harmful pesticide use and a major reduction in the use of herbicides. Many botanic gardens now work to ensure that almost all organic waste materials generated are composted, including waste paper from offices, much of which is now composted. In glasshouses, integrated pest management solutions are being increasingly applied as an alternative to using pesticides. A significant development in some botanic gardens is the creation of fruit and vegetable display and demonstration gardens, sometimes managed according to organic gardening principles. These often become the focus of public education programs in horticulture and are used for composting workshops as well as for gardening classes and demonstrating specific horticultural topics.

Encouraging and conserving wildlife in botanic gardens are also recognized as a component of their programs. This has

included the development of biodiversity inventories of the wild organisms found in the institution, including birds, insects, and other invertebrates, plants, and fungi (e.g., Willis and Morkel, 2007).

Promoting and Supporting Biodiversity Conservation

Support for the implementation of the UN Convention on Biological Diversity (CBD) has increasingly been mainstreamed into the activities of botanic gardens worldwide. In particular the Global Strategy for Plant Conservation has been adopted as a central component of the priorities and policies of many. The membership of Botanic Gardens Conservation International has steadily increased since its establishment in 1987, indicating enhanced interest in and involvement in biodiversity conservation issues. Several botanic gardens and their network organizations have become members of the Global Partnership for Plant Conservation (see www.plants2020.net), an informal network of leading institutions and organizations supporting the achievement of the GSPC.

Many botanic gardens maintain collections of plants that are listed by IUCN, or listed in national legislation, as threatened in the wild. Data on them are generally included in BGCI's on-line database, the Plant Search.

Supporting Sustainable Development Locally, Nationally, and Internationally

A range of activities are undertaken by botanic gardens to support sustainable development at various levels. This includes policy development, support for sustainable development initiatives, such as Fair Trade projects, the development of energy conservation, recycling, and other resource conservation initiatives. Capacity building for sustainable development is also a key function of many botanic gardens, which offer training places in horticulture, botany, conservation, and other disciplines. Such training opportunities are often made available to international participants, such as the International Diploma Courses offered by the Royal Botanic Gardens Kew in Botanic Garden Management, Botanic Garden Education, Plant Conservation Techniques, and Herbarium Management. Other botanic gardens carry out their capacity building and training initiatives in association with local universities and colleges, offering undergraduate and postgraduate degree opportunities.

Education for and about the Environment

Sustainability is a key and fundamental part of the education programs of many botanic gardens, much of which is focused on the theme of education for sustainability. Examples of specific programs in this area include an annual educational event organized by the National Botanic Gardens of Ireland, which hosts a special Sustainable Environment Fair each year. A range of environmental organizations are invited into the Gardens for the event and other activities are organized, such as an organic Farmers' Market, recycled wooden furniture sales, basketry and wood turning demonstrations, guided tours of our sustainability efforts, and sales of fair trade and

other products. The Missouri Botanical Garden in St Louis, USA undertakes a similar event, with an annual Green Homes and Great Health Festival where best practice and demonstration of up-to-date methodologies and technologies in sustainability are demonstrated. At the Missouri Garden a special department called 'Earthways' has become a leader in providing guidance, support, and mentorship for local communities, companies, and other organizations and groups in developing sustainable practices.

Recycling and Reducing Waste and Energy Consumption and Conservation

One of the greatest sustainability challenges for most botanic gardens has been in the area of waste reduction and recycling. Each year visitors to botanic gardens leave vast quantities of waste in litter bins and trashcans, all of which has to be disposed of. Some gardens have taken the approach of providing separate receptacles for recyclable and compostable materials. Others have removed waste receptacles entirely and ask visitors to carry away their own waste and dispose of it responsibly. A number of gardens operate a single-stream recycling program, where waste is separated after collection and segregated into compostable, recyclable and waste that goes to landfill. To assist this conversion of waste, some botanic gardens have introduced new compostable materials into their operations, such as compostable cups and other containers, as well as the removal of plastic water bottles from sale and the installation of new water-filling stations so that visitors can refill reusable water containers.

Some botanic gardens have adopted policies to reduce energy consumption and using energy from sustainable sources. This has involved retrofitting existing buildings in some cases to make them more energy efficient. Efforts are made to reduce minimum temperatures in the greenhouses, offices, and other buildings. A 'Turn down/switch off' campaign for staff is often adopted, sometimes promoted and guided by Green Teams, or groups of energy conservation officers chosen from the staff of the gardens and representing each area of the institution. Setting annual targets for energy consumption reductions has been found by some institutions to be the best way of achieving or monitoring progress in making energy savings.

Botanic Gardens and Human Health

Botanic gardens throughout the world have been linked to human health issues for hundreds of years. As discussed earlier, the first botanic gardens of the world, established in Italy nearly 470 years ago, were created to assist in the teaching of medical students as part of universities in Pisa (1543), Padua (1545), Florence (1545), and Bologna (1547). Elsewhere in Europe other early botanic gardens (Physic Gardens) associated with medicinal plant study include Zurich, Leiden, Leipzig, Paris, Montpellier, and Oxford.

There is a growing new awareness of the importance of plants for primary health care amongst botanic gardens, even

in today's modern world. This development can be traced back to 1988 when a ground-breaking initiative on Plants for Healthcare, the Chiang Mai Declaration, was developed by the World Health Organization (WHO), IUCN, and WWF. This reminded the world community that 80% of the world's people depend on traditional medicine for their primary health care needs. This gave rise to heightened awareness that the use of medicinal plants in primary health care needs to be recognized and safeguarded. In addition, the Chiang Mai Declaration led to the publication of new *Guidelines on the Conservation of Medicinal Plants* (WHO, 1993), which helped to promote international cooperation and coordination in medicinal plant conservation. The importance of plants for healthcare should not be underestimated. For example, traditional Chinese medicine alone uses more than 5000 plant species and traditional medicines in India are based on 7000 different species.

Today many botanic gardens maintain specific interests in medicinal plants, health care and in the promotion of human well-being. Wyse Jackson and Dennis (1998) recorded more than 440 botanic gardens that are known to maintain specific collections of medicinal plants. In that regard, there are key roles in medicinal plants played by botanic gardens in many developing regions, notably in countries such as Cameroon, China, Colombia, India, Sri Lanka, and Vietnam. The roles of such gardens include research on plant use in primary healthcare, studies on the sustainable harvesting and use of wild medicinal plant resources, and public education. In developed countries, particularly in Europe and North America, botanic gardens too continue to play roles in medicinal plants, specifically in areas such as raising public awareness and education and some aspects of pharmaceutical research, including bioprospecting for new sources of plant-based drugs.

The work of botanic gardens in medicinal plants is just one aspect of their role in global health promotion. Botanic garden work and priorities are increasingly directed towards managing and conserving biodiversity and ecosystems, both of which represent part of the fundamental foundations for human health and well-being.

The Millennium Ecosystem Assessment (2005) states that biodiversity is the foundation for human well-being. The World Health Organization's (WHO) contribution to the Millennium Ecosystem Assessment (2005) suggests that human health is strongly linked to the health of ecosystems, which meet many of our most "critical needs." Furthermore, the heads of the five biodiversity-related conventions recently stated:

Biodiversity can indeed help alleviate hunger and poverty, can promote human health, and be the basis for ensuring freedom and equity for all.

A report by Botanic Gardens Conservation International (Waylen, 2006) suggests that botanic gardens, through their biodiversity focused work, can make contributions to promoting human health and well-being, which can be categorized as follows:

- Improving healthcare
- Medicinal plant conservation and research
- Improving nutrition

- Poverty alleviation
- Community and social benefits.

Specific work undertaken by botanic gardens in this regard includes:

- *Ex situ* (off-site) conservation of medicinal plants, particularly those that are rare or endangered;
- Undertaking research in taxonomy, ecology, horticulture, ethnobotany, species conservation and biology, habitat restoration and management, and other areas;
- Public education;
- *In situ* conservation of plant resources in the wild (both wild plant species as well as crop plants and their wild relatives), in protected areas and in the wider landscape;
- Community-based programs, such as medicinal plant initiatives, city greening activities, and tree planting;
- Leisure services, such as the provision of green spaces for public relaxation;
- Collaboration with other bodies, organizations, and institutions in promoting healthcare and human well-being.

A recent report by BGCI (Hawkins, 2007) on medicinal plant conservation and botanic gardens elaborates on these aspects further and provides details on a wide range of examples from across the world.

Conclusion

The work of botanic gardens has adapted to changing needs and throughout time these institutions have contributed to social and economic development; from the early gardens founded to grow medicinal plants, to the eighteenth and nineteenth century gardens created for studies of economic botany and industry and trade development and more recently, the mobilization of botanic gardens to take an active role in *ex situ* conservation and support integrated conservation management. As our understanding of the impact of climate change unfolds and plant diversity faces increasing pressures, the work of botanic gardens will continue to adapt to address global priorities and meet society's need.

Glossary

Agroecosystem An ecosystem under agricultural management practices.

Biocontrol Control of agricultural pests by the use of predators and other beneficial organisms (e.g., control of turf grass crickets by parasitic nematodes).

Eutrophication The process by which a water body becomes enriched in dissolved nutrients (nitrogen, phosphorous) that stimulate the growth of aquatic plant life (e.g., algae), usually resulting in the depletion of oxygen from water. This frequently creates unfavorable conditions for fish and other biota.

Herbivores Animals feeding on plants only.

Mineralization Process of transformation from organic to inorganic form.

Soil food web Representation of all feeding interactions among the organisms in the soil (who eats whom).

Soil structure Spatial arrangement of soil particles.

Soil texture Percentile composition of clay, silt, and sand in soil.

Trophic Describing the feeding habits or the kind of nutrition used by a group of organisms.

Water-holding capacity Capacity of soil to hold water (e.g., sandy soils have very low water-holding capacity).

Definition of Soil

A Complex and Dynamic System

Soil is composed of living and nonliving components organized vertically, in a profile of horizontal layers or horizons. Soil is the habitat for a great abundance of diverse living organisms, many of which are microscopic (e.g., bacteria, fungi, protozoa, nematodes, and microarthropods) (Table 1). The nonliving component of soil consists of the solid phase, or weathered parent geological material, which contributes to the physical (e.g., soil texture, structure, density, and porosity

(the space within and between aggregates)) and chemical (e.g., fertility, moisture, and acidity) properties. The formation of soil is a function of climate, parent material, biota, and topography, which through geologic time has formed a multitude of natural soil types of varying properties across geographic landscapes (Jenny, 1980). Hundreds to thousands of years may be required to form just a centimeter of soil.

Role of Soil

Fertile or productive soils provide the basis of the economic wealth of a nation by providing food, fiber, and fuel. Soil supports human civilization by supplying nutrients for growth of plants, including agricultural crops, by regulating the water flow from rainfall to groundwater, and by filtering and transferring the harmful substances that might enter the atmosphere or groundwater (Wall, 2004). Water quality is largely dependent on the filtering capacity of the living and nonliving components of the soil. Soil is a natural resource, that contributes to the foundation of our social and industrial infrastructure.

Underground systems, as fundamental constituents of all terrestrial ecosystems, influence and are influenced by the functioning (the performance) of the aboveground systems. For example, soils affect the aboveground biodiversity, ecosystem nutrient and energy cycles and fluxes, and even certain atmospheric components (e.g., global cycles of C and N). Soils are one of the largest reservoirs of global carbon and are the major terrestrial reservoir of dead organisms – plants, animals, and microorganisms. The quality (chemical composition) and quantity of dead material (organic matter) received from both the aboveground and within the soil determine the primary nutrient and energy base for the soil biota. Plant litter (dead leaves, twigs, and roots) and other dead organic matter are decayed by soil microbial and faunal assemblages (organized in detritus food webs) during decomposition, a process of transforming organic matter to inorganic compounds

Table 1 Examples of some groups of soil fauna ordered by body width and the number of described species in soil

Soil fauna	Described species number
<i>Microfauna</i> (1–130 μ m body width)	
Protozoans	1500 ^a
Nematodes	24,379 ^b
<i>Mesofauna</i> (80 μ m–4 mm body width)	
Mites	42,000 ^c
Springtails	6284 ^b
Diplurans	976 ^b
Pot worms	600 ^a
Termites	2955 ^d
<i>Macrofauna</i> (1–35 mm of body width)	
Isopods	5000 ^a
Centipedes	2743 ^b
Millipedes	10,000 ^a
Earthworms	3600 ^a
Ants	11,000 ^e
Flies (larvae)	150,000 ^b

^aWall and Virginia (2000).

^bHallan (2007).

^cHalliday *et al.* (2000).

^dEngel and Krishna, personal communication.

^eFernández (2003).

Only about 1–5% of soil biota have been described to species level.

(e.g., nitrate, ammonium, and phosphate), which supplies nutrients for plant growth. Thus, the factors affecting the quality and quantity of soil organic matter (SOM), such as climate, cultivation, invasive species, and atmospheric nitrogen (N) inputs (e.g., acid rain), can alter the diversity of above and underground organisms, the rate of decomposition, the structure of soil, and the availability of nutrients needed for plant growth.

Soil Quality

Attributes of High-Quality Soils

In the broader sense, the quality of soil refers to an ability to sustain biological productivity and the diversity of plant, animal, and human populations, and to maintain quality of water and air. High soil quality also implies an ability of soils to maintain high fertility, productivity, and resist erosion. Natural differences in the quality of soils indicate different capacities of soils to resist stress whether of natural (e.g., wind, fire, and rainstorm) or anthropogenic (e.g., plow, invasive species, and pesticides) origin. In the narrower sense, soil quality relates to the inherent combination of biotic, physical, and chemical properties that allows soils to have long-term productivity.

A number of factors are involved in defining the quality and productivity of soils: parent material (the geologic weathering of rock), climate, SOM, soil structure (aggregation of soil particles), soil stabilization, and soil biota (including roots) (Coleman *et al.*, 2004; Bardgett, 2005). One of the most important factors is SOM. The amount and type of SOM and the products of decomposition affect several soil properties. A higher content of SOM results in higher cation exchange capacity (CEC), higher water-holding capacity, higher infiltration rates, better soil aeration, and increased soil particle aggregation, all leading to improved moisture infiltration and retention, reduced runoff of nutrients, and less soil erosion. CEC refers to the ability of soil to store nutrients (e.g., calcium, magnesium, and potassium) for future plant uptake. Organic matter, soil biota abundance and diversity, plant roots, and water and air movement affect soil structure formation and aggregation (Hartel, 1998; Paul and Clark, 1996). Soil stabilization, that is the ability of soil to maintain its structural integrity when subjected to natural or anthropogenic stress, occurs when there is some degree of aggregation of soil particles. The soils then become more resistant to soil degradation (e.g., erosion, loss of fertility, reduced filtering, and buffering capacity).

Erosion

Erosion is a general term for the removal of the earth's surface by abrasive actions of wind, water, waves, and glaciers. There are two types of erosion: geological and accelerated. The Grand Canyon in the US is an example of the effects of geological erosion that occurred over millions of years ago. Geological erosion in natural ecosystems is a slow process, typically occurring at a rate slower than the rate of soil formation. This is because the soil is protected by the vegetation process. For example, aboveground vegetation can reduce the

wind speed and hence the roots help in anchoring the soil. Accelerated erosion happens when the rate of soil loss is higher than the rate of soil formation. This type of erosion occurs when the lighter individual particles of soil aggregates are detached and transported by the wind or water. These particles can be blown to great distances as dust (the Dust Bowl of the 1930s in the US) and be deposited to form new soils or washed into streams, rivers, and oceans. The risk of soil erosion depends on the natural conditions (climate, slope, vegetation cover, and soil) and land use (e.g., removal of the protective cover of vegetation). Erosion results in a deterioration of soil quality and imposes hazards to humans and organisms in the terrestrial and aquatic ecosystems (e.g., loss of soil fertility, reduced plant productivity, loss of water and air quality, flooding, mudslides, and sedimentation).

Erosion is the primary factor degrading soils on a global scale (Figure 1). In many areas of the world, eroded land is no longer productive and is often abandoned. A recent estimate indicates the amount of arable land on earth is about 1.40 billion hectares (Figure 2) (Food and Agriculture Organization, 2010). In many areas, continuous intensive agricultural cultivation leads to soil erosion, salinization, and desertification and often to loss of the land from agricultural production. It is estimated that globally 25 billion metric tons of soil erodes each year from agricultural land (17 tons per cultivated hectare, or 4.5 tons per person) (Food and Agriculture Organization, 1992). To accommodate the rapidly increasing human population, global agriculture will have to increase the quantity or quality of food produced on a given area or increase cropland area into marginal areas of lower soil quality. Thus, the global efforts to conserve soils are of immediate importance for human well-being.

Water is estimated to be responsible for more than one-half of the global soil degradation, followed by wind, chemical (e.g., salinization, acidification, pollutants, atmospheric nitrogen deposition, excessive fertilizers, pesticides, and manures), and physical (soil compaction, water logging, and subsidence) degradation. However, whether a region is affected more by wind or water is dependent to a large degree on its climate. Wind erosion is a more serious problem for agricultural lands in the arid and semiarid regions of the world (e.g., North Africa, the Near East, parts of Asia, Australia, northwest China, southern South America, and North America). Salinization, the increased concentration of salts in the topsoil, can occur in the irrigated lands of the world due to increased evaporation, susceptibility of soils to salty groundwater, and invasion of seawater. These forms of soil degradation continue to decrease the availability of productive land for future food, fiber, and fuel production.

As high-quality and agriculturally productive land diminishes, other ecosystems (e.g., forests, wetlands, and meadows) become vulnerable. Over the past three centuries, 2.2 billion ha of forests (down from 4 to 6.2 billion ha worldwide) have been converted to agricultural lands. Forests generally have a high biodiversity and are a reservoir of hundreds of billions of tons of carbon stored in trees and soils. On a global scale, conversion of forests to croplands releases CO₂ into the atmosphere, contributing to the global warming. Conservation of soil is critical to the maintenance of sustainable ecosystems for the future.

Figure 1 Causes of degradation of the world's land surface. 1995. The percentage indicates the respective impact of the various forms of degradation. The "Other" section includes pollution (1.1%), overblowing (0.6%), waterlogging (0.5%), acidification (0.3%), and subsidence (0.2%).

Figure 2 Total world's land surface and reasons why the entire land on earth cannot be used for the agricultural activity. The percentage indicates fraction of total land, and numbers in parenthesis indicate the actual area in hectares (ha).

Effects of Conversion of Natural Systems on Soil Quality

In natural systems, the amount of SOM is maintained by high (generally greater than 90% of primary production) litter inputs, but in agricultural and grassland grazed systems due to harvesting the yield or herbivory, only about 50% of the primary production contributes to the SOM. In agriculture, the lower amounts of organic matter input to SOM results in less substrate (energy and nutrients) for the soil food web and fewer nutrients are available to plants over time. In intensive agriculture, nutrients removed by crops or lost with erosion of topsoil have to be replaced with synthetic fertilizers in order to maintain high productivity.

Human activity changes the chemical and physical properties, biodiversity, and quality of the soil. Agriculture (including forestry and grazing), urbanization, industrialization, and climate change are the most significant modifiers of the soil quality. Tillage (plowing), one of the most successful agricultural practices, has been used for centuries to reduce weeds, aerate soils, and break up compacted soils. However, tillage along with other intensive agricultural practices, such as application of fertilizers and pesticides, use of heavy machinery, irrigation, and monocropping have resulted in degradation of soils in many regions of the world. Intensive tillage destroys soil aggregates, redistributes and enhances SOM turnover by increasing the rates of decomposition, decreases the quality and quantity of organic matter, changes soil climatic conditions, and decreases soil moisture, soil food web complexity, soil fertility, and soil stability (Paustian *et al.*, 1997). These changes increase microbial activity, organic matter oxidation, soil compaction, and water runoff. The timescale of agricultural soil degradation varies from decades to a few years (in tropical soils) to a single rainstorm. The loss of topsoil depends on the original status of the soil quality, farming practices, climatic events, and the amount of topsoil (Jenny, 1980).

Construction (e.g., building of dams, urban development) and deforestation also contribute to an increased rate of erosion and the loss of soil quality. Local effects of soil degradation are manifested on a landscape scale (watersheds, rivers, wetlands, or oceans) through surface and groundwater pollution and soil sedimentation, impacting the quality of water and air, and resulting in economic impacts on the tourism and fishing industry.

Conservation and Restoration

Methods of Soil Conservation in Agriculture

The rate of soil degradation presently exceeds the rate of soil formation in systems impacted by humans (Jenny, 1980, 1984). All the vegetative productivity depends to a great extent on the nutrient availability in the soil, but in managed systems, such as intensive agricultural systems with continuous monocultures, a disproportionate amount of nutrients are removed from the system as crop yield. Although synthetic fertilizers renew the nutrient pool necessary for plant growth, they do not regenerate the quantity or the heterogeneity in the quality of SOM. Thus, slower decomposing organic materials

(e.g., fertilizers such as manures) are increasingly used to replenish SOM. Crop harvesting also leaves the soil bare and exposed to erosion by the rain and wind. Thus, the diminishing quality of the soil resources in natural and managed ecosystems, and the increasing demand for food, fiber, and fuel supply, has resulted in a reevaluation and selection of land management strategies that enhance longevity and quality of the soil ecosystems. These alternatives focus on maintenance of SOM, soil fertility, soil biodiversity, soil structure, and soil stabilization, and a reduction of soil erosion as a means of sustaining ecosystems for the long term.

The methods to reduce soil erosion are directed toward protecting the surface of the soil (topsoil) and include tillage practices (reduced tillage, conservation tillage, no till, minimum till or zero tillage – techniques that use specially designed machines and herbicides for minimal impact on the soil); diversified farming or cover crops; polycultures; adding organic composts or mulches; crop rotations; plowing techniques, such as contour farming (plowing at right angles to the land to create ridges to hold water); terracing (leveling areas on a slope to prevent water runoff); and timing of plowing.

The methods of agricultural soil conservation have proven valuable whether used alone or in combination. In the US, soil conservation methods have decreased the soil erosion rates so that only one-third of the agricultural lands are eroding faster than the average rate of soil formation. Although this is a considerable improvement over the Dust Bowl days of the 1930s in the US, soil conservation still appears to be necessary. A recent summary of the long-term experiments has evaluated the methods of conservation tillage intensity and crop management used alone or in combination on soil carbon storage. The combination of reduced tillage, bare fallow, increased inputs of crop residue, and crop rotations (with use of perennial vegetation) was more efficient at restoring the SOM and soil carbon and reducing levels of soil erosion than any of these management methods used separately. The rates of erosion were decreased in Creek Basin, Wisconsin, over the past 140-year period (historical and current data) because of the improvements in local agricultural land management from 1975 to 1993. These studies provide evidence supporting the efficacy of soil conservation practices.

Reduced Tillage

One of the most important factors decreasing the soil quality is tillage. Reduced tillage practices that incorporate crop residues retention in the soil are among the best alternatives for conventional tillage and have increased globally over the past 10 years. Although reduced tillage practices increase SOM and soil moisture and contribute in many cases to an improved soil food web, they may require a greater use of herbicides due to the establishment and spread of weeds and soil pathogens. In some situations, crop yields may decrease due to the presence of the weeds and pathogen diseases.

Conventional and reduced tillage systems appear to be economically comparable, particularly if crop rotation is used in the reduced tillage system. The reduced tillage system, however, promotes greater long-term benefits for ecosystems locally and globally. Soil biotic complexity is generally affected positively by the retention of crop residues, and the rate of decomposition generally changes from a microbial to a fungal

pathway resulting in a slower pulsed release of nutrients for plant uptake. The retention of soil residues also results in a reduction in CO₂ emissions to the atmosphere as compared to the conventional tillage, and a long-term conservation of beneficial chemical and physical properties of soil.

In conventional high-input agroecosystems, high crop productivity is achieved by the application of synthetic fertilizers (mainly nitrogen, potassium, and phosphorus), not by decomposition of SOM. As SOM diminishes in conventionally tilled systems, N and P retention is reduced and significant amounts of added fertilizers (nitrogen and phosphorus) are lost from the system. Fertilizer runoff and nutrient leaching reduces surface and groundwater quality. At a regional and global scale, nutrients from agricultural fields are lost to the atmosphere or lead to the eutrophication of coastal waters with effects on coral reefs, estuaries, and fisheries. For example, in the Mississippi River, the nutrient levels have doubled or tripled since 1950s, resulting in large algal blooms that deplete oxygen from the water, killing fish and shrimp, as well as other organisms.

In contrast, in most reduced tillage systems, the quantity of nitrogen applied as fertilizer is reduced, and there is an increase in the amount of applied nitrogen that becomes immobilized in the soil's organic matter. The nitrate leaching potential is reduced and subsequently the risk of water pollution is lowered. However, increased earthworm populations co-occurring with the reduced tillage practices can result in an increased soil porosity and higher nitrate leaching.

Diversified Cropping

Organic matter can also be conserved in soils by growing cover crops, termed diversified or multiple cropping, during fallowing. The advantages of cover crops are numerous. They not only reduce soil nitrogen leaching (nitrates become immobilized in plant biomass), but also provide a relatively effective means of weed control. They also decrease erosion since the plants and not the soil intercept the raindrops. Cover crops are selected based on several attributes, including plant species that improve soil (e.g., depth of roots, type of organic matter produced, and legumes that fix atmospheric nitrogen), their effect on plant pathogens and their predators, or for their economic benefits. Although multiple cropping requires an extensive knowledge of the type of crop, and in what sequence to grow cover crops, the benefits have been recognized for centuries. Multiple cropping systems are increasingly being used as a tool in modern agriculture. Today's research provides a scientific support for the diversified agricultural systems as they maintain soil quality (SOM, soil fertility), low insect and disease occurrence, and high plant productivity.

Organic Amendments

Organic materials or mulches in many instances offer a long-term option for maintaining soils with higher SOM in long-term agricultural production. Composts provide sources of nutrients that promote plant productivity and soil quality. Other benefits include improved soil aggregation, soil aeration, water-holding capacity, and CEC. Examples of organic amendments include green manures (herbaceous crops plowed under while green), chicken and cow manure, pig slurry, urban grass cuttings, and home garden composts of leaves,

grass, and food remains. When conformed to quality standards set by national environmental agencies, composts such as those derived from the municipal and industrial wastes have the potential to improve soil quality and at the same time reduce the conversion of land to landfills (land conservation). Currently, however, the supply of compost does not meet demand, and with the higher cost of compost as compared to synthetic fertilizers, the use of organic amendments is not an economical option for many growers in the industrialized nations. An increase of consumer interest in the purchase of organically grown food products may increase future use of composted organic materials.

Bioremediation of Pollutants

SOM, soil structure, fertility, and stability – and thus the soil quality – can be affected by pollutants. Chemical may be introduced to the soil system deliberately (e.g., fertilizers and pesticides) or accidentally (via spills or failures of technological processes). Depending on the final concentration, the presence of many hazardous and toxic chemicals can have an immediate or long-term effect on soil quality. Restoration of polluted soils through bioremediation not only avoids the risk of human and animal health hazards, but also restores, to some degree, the degraded land. Bioremediation, unlike other methods, takes advantage of soil biota or plants to detoxify the contaminants in the soil.

Soil is a natural habitat to diverse microorganisms and other soil biota that assist in the reduction of the soil contaminants. Microorganisms, for example, may use the pollutant as a substrate or energy source for their metabolism and change the composition of the compound to a less harmful chemical. Pollutants can be changed from harmful to environmentally safe compounds through natural bioremediation (use of indigenous microflora), biostimulation (addition of nutrients to soil to stimulate activity of indigenous microflora), bioventing (addition of gases such as oxygen or methane to stimulate activity of microflora), bioaugmentation (inoculation of soil with exogenous microorganisms), landfarming (mixing healthy and toxic soil), and phytoremediation (use of plants) (Skipper, 1998).

Bioremediation offers an interesting and economical alternative to the conventional way of cleaning soil contaminants. The entire treatment occurs at the polluted site as opposed to the more traditional method of moving large amounts of soil to treatment facilities and then back to the field. Bioremediation is often cheaper, resulting in savings of energy used to remove and transport soil, and typically has a lower environmental impact, as it depends on the natural processes with no hazardous byproducts (Skipper, 1998). The major constraints of bioremediation apply to the nature of the pollutants, as microorganisms cannot access many new synthetic compounds. Bioremediation can be further complicated by soil contaminants that are mixtures of pollutants, degradation of which may require the presence of several types of organisms each capable of transforming a different chemical in the mixture.

Manipulating the Biotic Community

Another aspect of soil quality relates to the diversity of biotic communities. Native land transformation, agricultural

management, and pollution significantly affect, in most cases negatively, the abundance and diversity of organisms (Foissner, 1999; Bardgett, 2005). The array of multiple plant species (trees, shrubs, grasses) seen in native systems contribute to the soil stabilization because the heterogeneity of rooting distribution, rooting depth, and plant chemical composition help to maintain soil structure and a diverse biotic community. In conventional agricultural systems, monocropping or cropping of one plant species (if not one variety) provides homogeneous root morphology, root depth, and litter quality across the landscape. The differences between the underground heterogeneity of natural systems and the underground homogeneity imposed by the monoculture agriculture must be considered when developing the long-term soil conservation plans. Using polycultures or intercropping is an agricultural practice that mimics, to some degree, the underground heterogeneity of natural systems. An unresolved question is whether creating or restoring the structure of soil by this practice will actually recreate and restore the function provided by the soil biota.

The abundance and diversity of microflora and fauna in soil provides beneficial services to humans and ecosystems, including, but not limited to, nutrient mineralization, biological control, nitrogen fixation, soil carbon sequestration, soil aggregation, and soil stabilization (Wall, 2004). In natural systems, the decomposition of organic matter (plant litter, dead roots, animals) to inorganic chemicals necessary for plant growth involves many different groups of soil organisms. Microflora (bacteria and fungi) influence the amount of C stored in the soil and are responsible for the global cycling of many minerals (e.g., N, C, S, P) (Gregorich *et al.*, 1997). Microflora play a critical role by aggregating the soil particles, which helps to prevent soil erosion. For example, they produce chemicals (e.g., polysaccharides) that bind soil particles, or have morphological structures (e.g., fungal hyphae) that connect the soil particles. Microfauna (e.g., protozoa, nematodes) affect soil fertility by trophic interactions with microflora that increase available N and P for plants. Nematodes, for instance, by grazing on bacteria can alter bacterial abundance and activity and thus significantly affect the rate of organic matter turnover and nutrient availability. Invertebrates transport microflora throughout the soil and in addition to functions similar to microfauna, mesofauna (e.g. mites and springtails) feed on fungi and other small fauna (Brussaard *et al.*, 1997). Macrofauna (e.g., earthworms, termites, ants, and snails) comminute and redistribute organic matter within the soil profile and by burrowing affect soil physical properties (Lee and Foster, 1991). They have been termed "soil engineers" for their role in mixing soils and microflora.

Tillage, monocropping, and addition of fertilizers and pesticides often reduce the diversity of many components of soil biotic communities, limiting at the same time their potential positive effects on many ecosystem processes. Improvement of soil quality will depend on the integrated management practices that reduce the artificial energy inputs (fertilizers) and exploit the food webs of soil organisms. Maintenance or exploitation of soil biodiversity for beneficial human services may require a significant change in intensive conventional tillage. Reduced tillage, for instance, promotes more diverse decomposer communities (often with a higher

fungal proportion) and lower mineralization rates (reduction of N losses). A long-term addition of organic matter (compost or no till) promotes microbial and faunal activities through which restoration of nutrients and SOM are possible. However, considerable research is needed to determine how these practices will affect the food web. Just as all soils differ in their composition, food webs vary with soil, climate, and the quality and quantity of organic matter. Therefore, different organic composts cannot be expected to create the same food web in all the soils.

Another way to maintain soil biodiversity and underground heterogeneity is the development of agricultural mosaics. A traditional agricultural process (still common in the tropics and many European countries) promotes a patchy landscape with the use of strip weed margins, hedgerows, and shelterbelts. The latter two types create vertical structures to reduce wind, and also provide microhabitats and refugia for many beneficial soil organisms. A huge area with a monocropping system increases the risk of pest outbreaks. Among many characters of agroecosystems with low pest potential are diversified crops in time and space, crop rotations, a structural mosaic of cultivated and uncultivated lands, the presence of perennial crops, and high crop genetic diversity. All these elements not only stimulate the development of favorable habitats for biological control agents, but they also provide a reservoir for recolonization of organisms involved in decomposition, detoxification, and other renewal processes.

Conservation of Urban Soils

Human population growth has been followed by urbanization. Conversion of the native land for housing, parking, roads, industry, landfills, mining, and so on, not only reduces potentially arable land but also affects global nutrient cycles (C and N). The additional consequences of urbanization include an increased use of the fertilizers and pesticides in home lawns and gardens. These contribute to the soil and water pollution, decreased soil biotic complexity, and increased nitrogen runoff. Alongwith the urban development it is important to adopt urbanization strategies that are environmentally safe. Proposed methods for environmental urbanization, including vertical rather than horizontal sprawl, smaller house acreage, and preservation of open spaces between developed areas are already being socially accepted and implemented. On a smaller scale, planning home gardens based on the local climate and natural vegetation is becoming more popular.

Assessment and Monitoring of Soil Quality

The goal of providing future generations with an opportunity for a high quality of life cannot be detached from the preservation or improvement of environmental quality. In order to evaluate the status or change of the environment, assessment, monitoring, and regulation programs are being developed. On the basis of monitoring data, farming strategies, urban development techniques, and industrial technologies are being modified to prevent further degradation of a particular system. Typically, to evaluate the quality of the soil system, or its state of sustainability, the system attributes are compared to the native or minimally disturbed reference sites. This procedure can provide an initial estimate of human

impact (e.g., agriculture, urbanization, and pollution) and through monitoring (an assessment of a soil ecosystem's attributes through time) give us a perspective on the positive or negative aspects of a management strategy. To be effective, monitoring has to be connected with the process of management decisions; therefore adjustments or modifications of management strategies should accompany these decisions (a process termed "adaptive management").

Indicators

Indicators are the measures that tell us about the status of the environment over time. Monitoring of, for example, air and water quality as well as CO₂ concentrations are officially regulated by many countries. There have been many indicators proposed for monitoring the soil quality status, but it has been difficult to select a single indicator that would aid policy makers.

The quality of soil can be defined in terms of many variables or combinations of variables. These variables include items such as biodiversity, levels of specific mineral elements and pollutants, levels of primary productivity, or profitability. Some aspects of high-quality soils may contradict each other. For instance, higher levels of nitrogen in the soil may stimulate primary production but may suppress biodiversity. The choice of an indicator is further complicated by the spatial heterogeneity of soils. Different soil systems may require a different suite of indicators. In addition, soil has many functions and maintaining those functions may have different impacts at different scales. For example, continuous cultivation may increase local crop productivity, but may deplete carbon stored in the soil, contributing to the globally elevated atmospheric CO₂. Theoretically, some optimal condition involving a combination of different aspects of the soil quality can be achieved.

Physical Attributes of Soil as Indicators

The ability of soil to provide mechanical support for plant growth, diversity of life forms, and agricultural activities is another measure of the soil quality. The most important physical attributes of potentially indicative functions of soil quality are soil porosity, soil stability, water storage capacity, aeration, and soil structure. Any of these measures would indicate a change in the soil quality, but might not indicate other changes that are important to the ecosystem function.

Soil porosity determines how well liquids, gases, and heat can be stored and transmitted within the soil matrix. A greater porosity often indicates greater storage and transmission ability. Soils have greater stability and resistance to natural and anthropogenic stress when the structural integrity of the soil is intact. Soil stability decreases with tillage, the use of heavy equipment, and heavy rainfall or irrigation, because soil aggregates are destroyed and greater compaction and erosion occurs. Soil water storage capacity is particularly important for the biotic component (plants, microbes, fauna) of soil ecosystems. The best plant performance occurs in soils almost saturated with water and declines as the soil dries. Many of the soil fauna are the aquatic organisms that require a film of water around soil particles for reproduction and mobility. The abundance and diversity of soil organisms can also be negatively affected by extremes in soil moisture.

Soil porosity and soil water content are directly related to soil aeration. Aeration is considered as an ability of the soil to store and transmit gases, particularly oxygen and carbon dioxide, as these are the components of roots, microbes, and fauna activity. Low porosity and waterlogged soils might induce an inadequate aeration and negatively affect the plant growth, root activity, soil biodiversity, and trace gas flux (methane).

These physical soil characteristics are inherently related to the soil structure. The extent, size, and shape of aggregates can strongly affect physical, chemical, and biological properties of the soil. Typical indicators of good soil structure are well-established aggregates with a desirable porosity, water-holding capacity, and aeration, resulting in more favorable environments for biodiversity and plant productivity as well as resistance to degradation.

Chemical Attributes of Soil as Indicators

In terms of chemical attributes, the major functions of soil are to store and supply sufficient amounts of nutrients to sustain an ecosystem's primary productivity and immobilize or detoxify hazardous compounds that are toxic to plants and animals. Among the chemical properties of soil the most useful as indicators of soil quality are mineralogy, organic matter content, CEC, salinity, and pH (acidity or alkalinity). Soil mineralogy determines bioavailability (adsorption and precipitation) and mobility of nutrients in the soil solution and is dependent on the content and type of silicate clay minerals and the content of Fe and Al oxide and hydrous oxide minerals.

SOM (or soil carbon) is usually the most important factor affecting the soil quality and productivity. SOM has a direct influence on physical and chemical soil characteristics and an indirect effect on plant production, and it is the major energy source for the abundance and diversity of soil organisms. SOM increases water retention and decreases runoff by preventing the sealing of the soil surface and promoting infiltration (and less erosion). When bound to the soil particles as aggregates, it improves soil structure. The upper part of the soil typically has the maximum SOM, generally about 1–10%, compared to 1% or less at greater depths. Mineral soils with high SOM are generally the most productive, and the carbon contained in the SOM is an important component of the global carbon cycle. Because of the positive correlation between high levels of organic matter and desirable attributes of mineral soil, it has been suggested as a reliable measure of soil quality. Even though changes in SOM are slow and vary locally and regionally, SOM is reliable as a long-term, rather than short-term, indicator of changes in soils.

CEC is another useful indicator of changes in soil quality. In general, a higher content of SOM and clay particles has a positive effect on the CEC. The soil pH can also significantly influence nutrient availability. For instance, Ca, Mg, and K deficiencies are often present in acidic soils, with Fe and Zn deficiencies appearing in alkaline soils. Trace elements and heavy metals may become more bioavailable in acidic soils. Plant productivity not only depends on the storage and supply of nutrients, but also on the ability of the soil to detoxify pollutants. Phytotoxicity and bioaccumulation may occur in areas under the strong influence of human activities (e.g., fuel

burning, mining, and industry) particularly in soils deficient in organic matter and low in CEC and pH.

Biological Attributes of Soil as Indicators

The environmental impact of human activities can be indicated, as outlined earlier, by the changes in the physical and chemical properties of the soil ecosystem. Despite their usefulness in characterization of the general status and quality of the soil, physical and chemical indicators have limitations. Do we know the biologically important thresholds of soil chemicals? Do we know how different sets of physical soil factors affect the bioavailability of soil chemicals? Are they stable enough to permit the detection of environmental change? Are they easily interpretable? How useful are the indicators across regional and global scales? These and other questions have led many scientists to examine other indicators.

As the biological attributes of the soil system directly relate and respond to the physical and chemical attributes, soil biota have been investigated as indicators of soil quality. Many organisms are sensitive to the changes in the physical and chemical properties of the soil–air or soil–water interfaces. Research shows that disturbances affect the soil biota differently depending on their physiology and life histories. Specific groups of organisms are associated with the soil at spatial (vertical vs. horizontal, rhizosphere vs. bulk soil) and temporal scales. Moreover, biota vary in their geographic distribution, therefore those groups of organisms that occur in all the soils (nematodes, protozoa, and microbes) are promising as indicators on a global scale, whereas those geographically limited groups (e.g., earthworms) may be more valuable on a local scale. The use of soil invertebrates as bioindicators might be problematic because the taxonomic and life history diversity of soil fauna requires extensive knowledge and training. As with the physical and chemical indicators of the soil, no single bioindicator has yet been proposed.

Microbes, protozoa, nematodes, mites, and earthworms are the most noted indicators for soil quality monitoring. Any changes in the community structure of soil biota can be based on a direct analysis of the dynamics of all identified taxa, or on data derived from taxonomic or ecological indices. Measures for comparisons of soil communities include traditional morphological data (species, genus, family, or functional group level), or more recently, molecular data (Porazinska *et al.*, 2010a, b; Wu *et al.*, 2009). As identification of soil organisms according to the species or genus level is difficult, a higher level of taxonomic hierarchy or functional group level is often applied. To relate the status of soil quality to the ecosystem change, the ecosystem processes driven by soil biota (e.g., decomposition, mineralization, and respiration) can be measured.

Many of the smaller organisms in soil share a number of attributes that are necessary for useful indicators. These include high abundance for ease of monitoring, occurrence in all soils (microbes, fungi, protozoa, and nematodes), sensitivity to changes in soil chemistry and pollutants (microbes, fungi, protozoa, nematodes, mites, and earthworms), sensitivity to soil physical changes (most taxa), and representation of a wide range of groups in the soil food web (nematodes, mites). Both protozoa and nematodes have been used to monitor the effects of pesticides and heavy metals. The

nematode community structure has also been used to illustrate the effects of natural ecosystem succession, environmental disturbance, and land management practices. Limitations to both protozoa and nematodes as indicators include difficulties in the enumeration and identification of species and their applicability at larger geographic scales. Recent advances in diagnostics using massive sequencing molecular data, however, might remove these limitations (Porazinska *et al.*, 2010a). Although common indices for abundance, diversity, richness, or rate of a particular process for different ecosystems may not exist, the applicability of bioindicators at a local scale might provide a powerful long-term tool for the soil conservation efforts.

Policies and Regulations

Adoption of soil conservation measures by farmers may not always be an easy choice. Surveys of farmers reveal that a conservation ethic is a less effective motivation for adoption of soil conservation practices than demonstration of economic benefits. However, farmers knowledgeable about erosion and soil degradation are more likely to adopt soil conservation practices than uninformed farmers. Thus, education and access to information are important aspects of any conservation effort, as are regulations and policies that conserve or sustain the land.

When private incentives differ from societal incentives, the influence of government policies and regulations can have a major impact on managing the natural resources. In the US, 25% of arable land is regulated with the beneficial effects for soil conservation. Conservation tillage in the US was part of the 1985 Food Security Act (FSA), which encouraged farmers to take erosion-control measures by providing farm subsidy payments. The US Food, Agriculture, Conservation, and Trade Act of 1990 (amendment to FSA) established financial penalties and ineligibility for most farmer program subsidies to farmers who produced agricultural crops on wetlands that were converted after enactment. This act also established the Conservation Reserve Program, providing an opportunity for the farmers to take highly erodible lands out of production by receiving annual rental payments from their 10-year contracts with the Department of Agriculture. The Federal Agriculture Improvement and Reform Act of 1996 introduced “planting” flexibility, giving farmers entering commodity programs freedom to choose crops on the contracted acreage. Under the same act, soil erosion control and wetland restoration regulations were improved. These few examples illustrate that government policies can slow land degradation.

The effects of land cultivation and soil erosion expand beyond the border of an agricultural field, state, or even country. Separate agricultural ecosystems are connected via a network of groundwater, streams, and rivers. Silt, sediments, nutrients, and other agricultural pollutants that are transported to streams, rivers, and ultimately marine systems can restrict the possibilities for navigation, irrigation, food production, and fisheries, and can affect water and air quality. Thus, the local ecological impacts of agricultural practices have been recognized globally. This has resulted in national and international policy frameworks including organizations such as: the Food and Agriculture Organization (FAO), the International Geosphere and Biosphere Program – Global Change in Terrestrial Ecosystems (IGBP – GCTE), the International Union of Soil

Science (IUSS), Global Assessment of Soil Degradation (GLASOD), and International Panel on Climate Change (IPCC), all of which have been active in either research, communication, or assistance to countries requiring immediate soil conservation measures and agricultural improvement.

There are also many international agreements whose policies include or are directed at ensuring soil sustainability. Agenda 21 is the action plan signed at the 1992 United Nations Conference on Environment and Development in Rio de Janeiro by the leaders from 169 countries. Agenda 21 devotes an entire article to sustainable agriculture and rural development both at national and international levels. Among many others, it aims for policies on land reform, less environmentally destructive developments, and conservation and rehabilitation of soil resources. Another example is the Convention on Biodiversity, which encourages agricultural practices that sustain biodiversity and ecosystem functioning. As our knowledge increases about the components of soil and their complexity, we realize that soil is a rare natural resource that should be used wisely.

Summary

Soils provide the basis for the world's food, fiber, and fuel production, as well as for the functioning of global ecosystems. They provide a habitat for a diversity of species comparable to the diversity of life above ground. Human activity changes the chemical and physical properties and biodiversity of the soil. Agriculture, urbanization, and industrial development are the primary activities that are accelerating the loss of soil quality. As ecosystems are so interconnected, degradation of soils has detrimental effects on all life. Practices exist that can be selected to conserve and allow the sustainable use of soils.

The most effective methods improving the quality of agricultural soils are reduced tillage, cropping mosaics, multiple cropping, crop rotations, and the application of organic amendments. Not only do they prevent further loss of SOM and soil carbon (anWashington, DC: National Academy Press important property of soil environments), but they also prevent loss of other favorable physical and chemical soil properties. To determine the status of soil environment, assessment and monitoring programs are being developed. Soil quality can be estimated with the use of various indicators reflecting physical, chemical, or biological soil attributes. The collected information serves as a basis for evaluation and modification of current management methods. Different soil ecosystems may require different suites of indicators.

When private incentives differ from societal, government policies and regulations can have a pronounced impact on managing soil resources. Since the problem of soil degradation crosses spatial scales (local, regional, and global), development and implementation of national or international policies is essential.

Glossary

Biodiversity The variability among living organisms from all sources, including diversity within species, between species, and of ecosystems.

Ecosystem services Ecosystem functions involving exchanges of nutrients, energy, waste, and materials through the interactions of organisms and the physical environment that contribute to human well-being.

Human well-being Meeting of physical, psychological, and spiritual needs through material security, health, social relations, personal security, freedom, and other factors.

Inclusive wealth The summed total of capital assets or human and Earth system properties that can be used to provide the flow of goods and services that contribute to well-being.

Intergenerational equity Equality and fairness in well-being of people in future different generations relative to current generations.

Natural capital The capacity of the natural world to provide services that contribute to human well-being. These may include providing services including food and fiber

production; regulating services, such as water flow and quality, or temperature regulation of the atmosphere; cultural services, such as recreation or meeting spiritual needs; and provision services such as soil formation and nutrient cycling.

Poverty A multidimensional concept that describes the inability to meet human needs; it includes economic, human, political, socio-cultural, and protective aspects of human capabilities, including income, livelihoods, health, education, empowerment, rights, status, dignity, and vulnerability.

Shadow prices The added value (or inclusive economic value) of an additional unit of a capital asset, such as widgets, regulation of the Earth's climate system, or human knowledge.

Social equity The fair, just, and equitable distribution of the stocks or flows of capital assets that contribute to human well-being.

Sustainable development The process of meeting human needs of the present without compromising the ability of future generations to meet their own needs.

Introduction: Biodiversity and Sustainability

Biological systems exhibit extraordinary diversity, whether considering the genetic variation within species, the differences among the more than 8 million recognized species found on the Earth, or the range of environments inhabited and shaped by those organisms. Over the past two centuries, the expansion of human populations, resource demands, and influence on the Earth's landscapes is the driving force behind a dramatic, planet-wide reduction in biodiversity at all of these levels (genes, species, and ecosystems). Estimates of species extinction over that time period range from 100 to 1000 times background levels (Millennium Ecosystem Assessment, 2005), a magnitude of biodiversity loss that has been matched only five times in Earth's history, and the first mass extinction known to be caused by a living species. That this catastrophic loss of diversity is linked with a dramatic increase in both the human population and its overall well-being raises fundamental questions for efforts to provide for human needs and preserve the planet's biodiversity, including whether the human population and its well-being can be maintained in the face of declining biodiversity.

The idea of sustainability – that the fruits of nature, if harvested at moderate rates, may be reaped indefinitely – is

ancient wisdom. However, translating that verity into workable policies is difficult and elusive. As economies and human population (Figure 1(a)) have grown rapidly during the past 200 years, exploitation of ecosystems for human gain has usually ignored sustainability and often depleted biodiversity. This may change in the next several decades as land transformation and human appropriation of ecosystem services surge toward natural limits and the growth rate of the human population declines toward zero. Still, more than 950 million people face hunger during at least a part of each year (14% of world population) emphasizing the tension between priorities for human welfare versus those for the conservation of species and ecosystems.

Should attempts to improve the material conditions of human life be constrained by attempts to ensure the long-term survival of habitats and species? The connection between sustainability and biodiversity is neither conceptually clear nor practically straightforward, but it is of fundamental significance. Whether slowing the loss of biodiversity is necessary or sufficient for the transition to a sustainable society depends not only on the material relationships between diversity and the provision of ecosystems services to human society, but also on the philosophical basis for the value of biodiversity. The three central rationales that have motivated biodiversity

Figure 1 Human demography trends. In recent decades, world population has increased exponentially reaching 7 billion (a) although annual population growth has slowed (b) as human fertility rates have declined (d). Infant mortality rates have declined (c) whereas life expectancy has increased (e) providing an indication of increases in human well-being. Meanwhile, most humans now live in urban environments because the fraction of the population in rural regions has consistently declined whereas that in urban populations has consistently increased over the last half century (f). Data from the World Bank (www.worldbank.org) and the Population Reference Bureau (www.prb.org).

conservation can be summarized as: (1) the ethical perspective that other organisms that evolved over millennia have a right to exist and a claim to planetary resources irrespective of human needs, (2) spiritual and cultural practices that value the existence of other organisms, and (3) empirical linkages between biodiversity and the provision of ecosystem services. Although these rationales are philosophically compatible and even overlapping, they have divergent implications for the prioritization of biodiversity conservation and the meeting of human needs. The ethical perspective (1) suggests that preservation of biodiversity should be considered a priority equal to human well-being. The spiritual/cultural perspective (2) takes as given that human well-being is dependent on the preservation of other species. In either case, a trajectory of development that erodes biodiversity is, by definition, unsustainable. Although both views motivate biodiversity conservation, they do not consider the contributions of biodiversity to the material well-being of society. As such they are likely to fall short in conflicts over land-use

that highlight immediate trade-offs between biodiversity conservation and production of goods and services for human consumption.

The ecosystem services justification is fundamentally anthropocentric, in that it makes the value of biodiversity contingent on its relationship to human well-being. Despite the weak philosophical protection it affords to biodiversity conservation, the potential for the ecosystem services perspective to align conservation and human development goals gives it the greatest prospects for widespread political adoption (MEA, 2005). In 1987, the World Commission on Environment and Development (WCED) chaired by Gro Harlem Brundtland declared: "Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs." Under this directive, the transition to sustainability will require that we understand the complex and reciprocal relationships between biodiversity and human well-being, both now and in the future.

Box 1 Sustainability and the theory of inclusive wealth

In theory, inclusive wealth considers all the contributions to human well-being from all planetary resources. These “capital assets” support, provision, and regulate goods and services now and in the future. The well-being or utility of individuals (U_i), who exist within a social state, x , where the social state characterizes everything that might influence well-being. Social well-being at time t $V(x(t))$ is an aggregate function of the well-being of individuals in society

$$V(x(t)) = V(U_1(x(t)) \ U_2(x(t)) \ \dots \ U_n(x(t)))$$

Social well-being from time t forward is measured by

$$V(t) = V(x(t)) + V(x(t+1))/(1+\delta) + \dots$$

where δ is the discount rate by which future values are discounted when compared to present values. The discount rate is an area of much controversy. Perhaps the well-being of future generations should not be discounted at all, or perhaps discounting is reasonable. Leaving aside the controversy, sustainability is said to be achieved when the flow of well-being is nondeclining, $dV/dt \geq 0$. Since well-being is subjective and not directly observable sustainability cannot be measured in this way. However, we can attempt to measure assets and their values. The theory becomes more tangible if we consider human well-being in terms of all of the capital assets or system properties, $K(t)$, that can be used to provide the flow of goods and services that contribute to well-being

$$V(t) = V(K(t), M)$$

where $K(t) = (K_1(t), K_2(t), \dots, K_H(t))$ and M is the evolving political economy or the resource allocation mechanism that involves institutions. Capital assets that contribute to well-being come in many forms, including manufactured capital, natural capital, human capital, social capital, and knowledge capital. Taking the derivative of $V(K(t), M)$ with respect to time generates the following expression:

$$\frac{dV(K(t), M)}{dt} = \sum_{h=1}^n \frac{\partial V(K(t), M)}{\partial K_h} \frac{dK_h(t)}{dt}$$

The added value of an additional unit of capital asset h is its ‘shadow price’ P_h and can be defined as

$$P_h(K(t), M) = \frac{\partial V(K(t), M)}{\partial K_h(t)}$$

Inclusive savings or investment in capital asset h is

$$I_h(t) = \frac{dK_h(t)}{dt}$$

Inclusive wealth, which is the value of all capital assets, is

$$W(t) = \sum_{h=1}^H P_h(K(t), M) K_h(t)$$

and the change in the value of inclusive wealth through time is given by

$$\frac{dW(t)}{dt} = \sum_{h=1}^n p_h(K(t), M) \frac{dK_h(t)}{dt} = \sum_{h=1}^n p_h(K(t), M) I_h$$

Nondeclining social well-being through time is equivalent to nondeclining inclusive wealth, so that we can summarize sustainability from the perspective of the theory of inclusive wealth as being a trajectory through time where the total value of all capital assets that contribute to human well-being is nondeclining:

$$\frac{dV(K(t), M)}{dt} = \frac{dW(t)}{dt} = \sum_{h=1}^H P_h(K(t), M) I_h(t) \geq 0$$

A major challenge for the integration of biodiversity conservation and providing for human well-being through the framework of sustainability is the appropriate valuation of biodiversity. This challenge begins with determining the relationships between biodiversity and ecosystem function, and between ecosystem functions and their value in terms of well-being, relationships which are incompletely understood. But it also extends to and ultimately resides in questions of scale and equity, both within and among generations. That is, measures necessary to meet human needs locally may compromise biodiversity globally and vice versa,

and measures necessary to meet human needs or maintain biodiversity today may compromise one or both of these aims in the future. How can we determine the course that provides greater benefit to human welfare now or for humans in generations to come? A framework that considers inclusive wealth (Box 1), or the contributions of all natural and human-derived systems to human well-being, may help guide this search.

At the heart of potential tradeoffs between biodiversity conservation and human well-being are decisions about alternative land-uses, which must balance conservation against

uses that contribute immediately and directly to human welfare, such as agricultural production (Foley *et al.*, 2011). These are entangled with issues of equity by the fact that the world's biodiversity hotspots tend to be found in countries with the highest human population density and the lowest per capita income (Figure 2). These same countries, mostly in the tropics, have seen much of their best agricultural land committed to the production of sugar, tea, coffee, chocolate, and other luxury goods for temperate-zone markets for centuries, and increasingly to meet rising global demand for soya and palm oil in biodiversity hotspots such as Indonesia and Amazonia. Ultimately, the possible paths toward sustainability are constrained by the realities of the history and geography of human society and Earth's biodiversity.

The complexities of relationships among biodiversity and human well-being present fundamental challenges to defining the objectives of a sustainable future; thus a transition toward sustainability must be a search rather than a march. Regardless

of the specific path, a transition toward sustainability – in which biodiversity and the ecosystem services they provide are sustained and human needs met now and in the future – will require significant social, political, and technological changes during the next few generations. The good news is that this is a time period in which human population is expected to level off within the century due to declining fertility rates (Figure 1(d)); hence, it is possible to think of a sustainability transition on the timescale of the demographic transition drawing to a close during the twenty-first century. At the same time, even present levels of human population and consumption have proven devastating to the planet's biota. Understanding how past and future biodiversity loss influence the ecosystem and environmental services that contribute to human welfare is critical to the search for a sustainable future. Awareness of long-term trends and transitions, together with indicators to inform our searches, are important contributions that science can provide in addition to developing means for

Figure 2 Bird diversity (a, b), vascular plant diversity (c, d), and mammal diversity (e, f) by country in relation to population density (people per km²) and Gross National Income (GNI; \$US), respectively. GNI is the value of all products and services generated within a country in one year (GDP) plus the income lost to or gained from other countries through debt and interest payments. The relationships show that species diversity, one measure of biodiversity, is highest in countries where population density is highest and income is lowest, posing challenges for biodiversity conservation. In a–f, each point represents a single country. Lines are least squares regressions fitted to the data. Species per km² are calculated from the number of species per country divided by the total area of the country. Data on bird, mammal and plant diversity are from the World Resources Institution (earthtrends.wri.org); population density and GNI data are from the World Bank.

reconnecting human prosperity to the diverse and essential riches of the natural world.

Sustainability, Sustainable Development, and Carrying Capacity

The definition of a sustainable material economy remains problematic: Which stocks must be preserved? Which flows must be conserved and at what levels? Is there a single numeraire that can indicate sustainability or its opposite? There are no definitive answers to these questions, but the definition of sustainable development put forward by the Brundtland Commission (meeting the needs of the present without compromising those of future generations) contains within it two key concepts: The concept of needs, in particular the essential needs of the world's poor with an emphasis on alleviating poverty; and the idea of limitations imposed by the state of technology and social organization on the environment's ability to meet present and future needs.

In a simple consumer–resource interaction, resource use, or consumption is sustainable when the rate of extraction is equal to or less than the rate at which the resource can replenish itself. In such systems, for a given extraction rate and replenishment rate, there exists a finite limit (or carrying capacity) of the size of the consumer population, which can be sustained. When consumers exceed the carrying capacity, this can result in a self-limiting feedback, because with a decline of the resource base, the consumers' abundance also declines. In this light, ecosystems are essentially suites of resources that support both human and other organisms. And as such, they also have a finite limit (or carrying capacity) to support other populations. However, for humans, self-limiting feedbacks rarely manifest themselves as they would in a simple consumer–resource relationship. People obtain highly diverse and complex portfolios of resources and services from ecosystems, which allows numerous forms of buffering from self-limitation. Some resources can substitute for others in maintaining livelihoods. Thus, with some notable exceptions, the birth and death rates of human populations are rarely in lockstep dependence with a single ecosystem service. Also, our consumer–resource interactions are frequently spatially buffered. Humans live and work in virtually all parts of the planet, exchanging goods in a global economy. Richer societies have often transferred the burdens of their unsustainable practices onto poorer ones by harnessing goods and services produced in poor regions, and avoiding some of the costs of those goods in the form of environmental degradation. Humans have also developed technological innovations that buffer us from the harsh consequences of exceeding carrying capacities by enhancing the rate of resource replenishment, as is the case with fertilizer use on crops. And there is of course temporal buffering, wherein the consequences of unsustainable resource use do occur but are unobserved because the feedbacks take decades to play out.

For nearly all human populations, trends during the past several decades in indicators of well-being, such as declining infant mortality rates (Figure 1(c)) and increasing life expectancy (Figure 1(e)), income and education, indicate that human welfare is increasing. However, given the many ways by

which we buffer and escape direct suffering even when we exceed carrying capacities for ecosystem services, this outcome may not be entirely surprising. Buffering mechanisms, changes in social organizations, technological advances, and the values we place on different indicators of well-being can all obfuscate the finite nature of resource availability. However they do not change the fact that resources are still ultimately finite. They also do little or nothing to direct attention to the ways that overutilization of one resource can impact the availability of other resources and services. The destruction of biodiversity may be deemed a negligible cost to increasing ecosystem services like food production, but when we reduce a resource's abundance, we reduce the carrying capacity for other organisms that rely on the resource. This can lead to cascading losses of biodiversity, which comes full circle to limit resources on which humans depend. This cycle can be seen in the collapse of fisheries, the loss of species in logged tropical forests, and loss of agricultural soil productivity – all cases where exploitation of one resource has led to unexpected losses of other resources and services.

As human numbers and consumption of natural resources increased over the last century, so did concern that the impact of our species on the natural world would have irreversible, ultimately self-destructive effects. Using the idea of carrying capacity as a framework, ecologists have estimated that humans now appropriate slightly less than half the net primary production on land and approximately the same fraction of fresh water (Vitousek *et al.*, 1986). Such estimates indicate that further economic growth or improvements in human well-being – even if they occur – may not continue to increase the size of the material economy on which life depends. Indeed, it seems likely that achieving sustainable economies will require decreasing the burdens of wasted energy, discarded materials, and pollution that are now imposed on the environment. Technology plays a strategic role in this aspiration.

The Inclusive Wealth Framework for Sustainability

There are many perspectives from which to consider sustainability ranging from single indicators of human well-being that mimic Gross Domestic Product (GDP) to composite indicators to even more complex approaches. One type of approach, dubbed the 'dashboard' (Stiglitz *et al.*, 2009) involves gathering and analyzing a series of indicators that are relevant to evaluating environment, social, and economic progress simultaneously. At small spatial scales, particularly in agroecosystems found in many regions of Latin America, once such dashboard approach, the Framework for the Evaluation of Natural Resource Management Systems Incorporating Sustainability Indicators (MESMIS) has demonstrated promise (Speelman *et al.*, 2007). MESMIS considers indicators to evaluate system sustainability in the environmental, economic, and social arenas and provides criteria for sustainable management systems that emphasize (1) productivity, (2) stability, resilience and reliability, (3) adaptability, (4) equity, and (5) self-reliance. The effort has provided critical guidance in decision-making at the community level over the past decade. At larger spatial and sociopolitical scales, such as at national or global levels,

the inclusive wealth economic framework (Arrow *et al.*, 2004; Dasgupta, 2008), provides a theoretical framework for developing composite indicators and charting a path for sustainability (Box 1). The inclusive wealth framework follows an economic approach that defines sustainability as nondeclining human well-being over time. In doing so, it takes a strictly human-focused perspective thereby ignoring the value of planetary resources for other species unless they benefit humans. However, it does allow for valuing of biodiversity to humans spiritually, materially, and for their importance in providing ecosystem services. Acknowledging this tension, the inclusive wealth framework offers guidance for human decision-making for achieving sustainability considering resource use, ecosystem services, and human well-being.

Human well-being is difficult to define, given its subjective nature. It is a function of material security, health, social relations, personal security, freedom, and other factors. Essential to human well-being is that physical, psychological, and spiritual needs which are met. In keeping with the United Nations World Commission on Environment and Development (WCED) (1987) definition of sustainable development, a sustainable development path is one in which human well-being is nondeclining. A sustainable economy, therefore, is one which follows a development trajectory in which intergenerational well-being is nondeclining.

Inclusive wealth includes the contributions to wealth from all capital assets and the value of these assets is determined by their contribution to the current and future production or provision of goods and services (Box 1). In other words, sustainability is achieved if the change in the total value of all capital assets that contribute to human well-being and investment in those assets is nondeclining.

Theoretically, it is possible to calculate changes in well-being through time by tracking the change in inclusive wealth, which is a function of both the shadow prices of capital assets and investment or depreciation in the capital assets that contribute to well being (Box 1). The theory provides an elegant means to focus attention on what needs to be measured to evaluate sustainability. Actually measuring inclusive wealth, however, presents an extreme challenge given that it requires quantifying shadow prices, a process fraught with difficulties and unknowns. Evaluating shadow prices for natural resources, for example, requires evaluating losses in terms of all present and future well-being that would result reductions in these resources. This necessitates understanding exactly how assets contribute to provision of goods and services and how goods and services contribute to human well-being; achieving such estimates for spiritual, aesthetic, or nontangible goods may be particularly problematic. Provisioning of environmental services depends also on systems dynamics and how evolving conditions will impact the stocks and flows of capital assets. In particular, the risks associated with catastrophic changes (i.e., tipping points) are difficult to assess and therefore to manage appropriately. Present formulations of inclusive wealth do not generally include how capital and services are distributed within or among economies. Although equity considerations can be incorporated into this framework, the real challenge is achieving societal agreement on how this is best done. Despite the many challenges, which highlight the nature of the search rather than a march toward sustainability,

Table 1 Examples of ecosystem services

<i>Supporting</i>	<i>Regulating</i>
Nutrient cycling	Global Climate regulation
Soil formation	Flood regulation
Primary production	Disease regulation
Oxygen production	Water purification
Pollination	Shade/temperature regulation
<i>Provisioning</i>	<i>Cultural</i>
Food	Aesthetic
Freshwater	Spiritual
Wood and Fiber	Educational
Fuel	Recreational
Pharmaceuticals	Identity

the inclusive wealth framework provides one approach to considering sustainability that incorporates the stocks and flows through time of the major forms of capital assets that contribute to human well-being.

Capital assets that contribute to human well-being go far beyond resources that are typically valued in monetary terms. All of the planetary and human-created resources that influence human welfare must be considered. These assets can be broken down into major categories, including (1) manufactured capital, which includes all the goods and services produced by humans, (2) human resources and capabilities, such as human health, human knowledge, and governmental, social, and cultural institutions, and (3) natural capital, which includes all the goods and services provisioned, regulated, and supported by Earth systems (e.g., the atmosphere and climate; terrestrial, freshwater, and oceanic ecosystems; and so forth) (Table 1). Natural capital assets, for example, include system properties such as soil, hydrology, vegetation, habitat, interactions between species and trophic levels, etc. that provide ecosystem/environmental services that contribute to human well-being. Such services include plant pollination, pest regulation, pollution reduction, renewable resource conservation, soil fertility, food and fiber production, freshwater, regulation of water flow and quality, flood regulation, nutrient regulation, carbon sequestration, disease regulation, recreation, aesthetics, pharmaceuticals, etc. Biodiversity is a critical component of natural capital assets from which these services flow (section Biodiversity as a Form of Natural Capital). Ecosystems and Earth systems, more generally, provide services in often complex and interacting ways that are often poorly understood and monitored. The maintenance of natural capital assets and their ability to provide services are influenced by human use and management. The governance, institutions, cultural values, social relations, incentives, regulations, markets, and so forth that drive how humans use and manage these assets are thus critical to the maintenance of and investment in natural capital.

Biodiversity as a Component of Natural Capital

Biodiversity represents a distinct component of natural capital and is often considered essential to sustainability. Species

extinction is one of the only indications of irreversible environmental loss widely accepted by laypersons; what is its practical significance, both biologically and socially? Is human well-being dependent on the survival of biodiversity, and if so how?

First, it is worth remembering that whereas biodiversity is often used to refer to the richness of species in a given region, it is a much broader term that includes the sum total of the living resources on Earth. According to the 1993 Convention on Biodiversity, biodiversity is the variability among living organisms from all sources, including diversity within species, between species and of ecosystems. The variety of life this encompasses as well as the complex and dynamic relationships among components of biodiversity make it much more than simply the number of species per unit area.

Second, an increasing number of scientific studies demonstrate empirical linkages between biodiversity and ecosystem services that contribute to human well-being (see article from Quijas and Balvanera, *Links between biodiversity and ecosystem services*). Quantitative syntheses of the large amount of experimental studies that have manipulated species richness and measured multiple ecosystem functions have shown that higher biodiversity provisions more services such as increased stability in the face of perturbation, higher productivity and thus higher provision of food fodder or wood, and better regulation of erosion, pests, and pathogens.

Ehrlich and Ehrlich (1981) hypothesized that losses of biodiversity have consequences for ecosystem function much like losses of redundant rivets in airplane wings: Initial losses of species should be accompanied by minimal change in the functioning of ecosystems because some fraction of species are redundant in the processes they perform in nature. However, at some point, loss of species lead to rapid declines in ecological function, much like the loss of one too many rivets can lead to failure of an airplane wing. Of the hundreds of scientific studies that have examined the empirical links between biodiversity and ecosystem functions, such as nutrient cycling and productivity, the vast majority support the rivet-redundancy hypothesis for individual ecosystem functions (Cardinale *et al.*, 2011). In agricultural systems, for example, different crop varieties that can adapt to altered climates or are resistant to different diseases provide redundancy and reduce risks. In the face of climate change or invasive pathogens, if one crop variety fails, another may persist. If one pollinating insect species declines, a similar species may provide the same service. Meta-analyses that have examined multiple ecosystem services simultaneously (Hector and Bagchi, 2007; Isbell *et al.*, 2011) demonstrate, however, that many more species are required to provide multiple ecosystem services than a single service alone. Such multidimensional investigations demonstrate that although each ecosystem function or service may depend on only a fraction of the species in the ecosystem, the number of critical species continues to increase as more functions and services are considered. The end result is that that most species, including rare species, turn out to be critical to the integrity of ecosystems.

Despite the wealth of evidence linking biodiversity to human well-being in experimental and theoretical contexts, at landscape, regional, within country, and among countries spatial scales, biodiversity, and ecosystem services may be at

conflict, given competing land-uses. Agriculture, for example, contributes to food provision at the cost of preserving habitat for other species. In contrast, a forest preserve allows for the maintenance of multiple species, which contributes to the maintenance of carbon stocks and the regulation of water-availability and related services, but does not allow for the extraction of timber or other products for human consumption.

It is possible to design landscape management schemes that allow for the simultaneous maintenance of biodiversity and agricultural areas (Porter-Bolland *et al.*, 2011). Diverse agroecosystems can be established within a matrix of conserved forest patches that allow for multiple species to find suitable habitat, while food is produced. Also, it is possible to design a network of sites for conservation that could maximize the conservation of biodiversity and that of ecosystem services. By identifying the key areas for conservation of biodiversity and those for the provision of ecosystem services, sites can be chosen to maximize both. Well-managed natural ecosystems that conserve biodiversity can provide income and jobs through trade, tourism, crafts, and sustainable food production. At the same time, productivity of existing agricultural systems in regions where they fall woefully short of possible production could prevent unnecessary expansion of land conversion to agriculture (Vandermeer and Perfecto, 2007; Foley *et al.*, 2011; Tilman *et al.*, 2011). Polasky and colleagues (2008) modeled an “efficiency frontier” of possible land-use scenarios in which biodiversity and economic output can both be increased far beyond current land management practices. Such options provide a path forward toward sustainability while recognizing that there are challenges, costs, and both winners and losers in the transition.

Biodiversity, Poverty, and Equity

Around the world, the Convention on Biological Diversity has unified nearly every country in a commitment to reduce the loss of biodiversity. Likewise, there is almost universal adoption of poverty reduction as a national goal, as evidenced by the widespread embracement of the Millennium Development Goals (Barrett *et al.*, 2011). These may seem on the surface to be independent endeavors, but they are important, complex interactions between the dynamics of poverty and biodiversity, occurring across spatial and temporal scales.

The well-known latitudinal gradient in biodiversity from the poles to the equator corresponds to a latitudinal gradient in poverty and human population, such that hotspots of biodiversity are found in some of the world's poorest and most densely populated nations (Figure 2). The interactions between biodiversity and poverty can lead to complex feedbacks that: synergistically benefit both biodiversity and poverty; create tradeoffs between aims to alleviate poverty or conserve biodiversity; or create detrimental feedbacks that eventually lead to worsening human and environmental conditions (Roe *et al.*, 2011). Therefore, the dual aims of biodiversity conservation and poverty reduction cannot be addressed independently of each other, nor can they be strictly pursued within nations without considering global dynamics. Instead, we must recognize and understand the relationships

that exist between biodiversity and poverty, and evaluate them integratively at local, regional, and global scales. Social and economic equity arises as a cross-cutting issue, shaping the trajectories of human–environment interactions and thus affecting sustainability.

At global, continental, and many national levels, trends indicate increases in average standards of human well-being despite declines in biodiversity (MEA, 2005). This would suggest that biodiversity conservation is not relevant to, or not necessary for, human development. However, such aggregated scales blur the fact that national average indicators of well-being can increase whereas the economic welfare of the poorest is stagnant or decreasing. Furthermore, when we focus on regions with extreme poverty, these areas are frequently regions of the greatest rates of biodiversity loss. Numerous factors contribute to this troubling co-occurrence.

Such regions are most commonly located in the tropics and in developing countries, where people often engage in traditional subsistence or small-scale production systems. These segments of society tend to rely heavily on local biodiversity to meet an array of their livelihood needs – food, fiber, fuel, construction materials, medicine, pollination

services, cultural services, etc. Also, these societies also tend to have high levels of multiple indicators of poverty, such as little wage employment or cash income, poor access to education, health, and social services, and political marginalization (Figure 3). This leads to a spatial correlation of biodiverse areas and poverty.

A major driver of biodiversity loss globally is demand and consumption of natural resources from urban areas and from the developed or rapidly developing world (DeFries *et al.*, 2010). Urban populations have continued to increase in all parts of the globe over the last century (Figure 1(c)) with increases in consumption that put pressure on agriculture and the natural resource bases at the expense of biodiversity. The loss of biodiversity in poor rural areas of developing countries occurs as local residents and governments are driven by such demands to exploit their natural capital to increase national economic growth. Natural resource extraction and land conversion – such as timber extraction, mineral extraction, expansion of agriculture or aquaculture, and urban growth – are often undertaken in environmentally irresponsible ways, due to some combination of weak governance, perverse incentives, and economic desperation. Whether out of economic necessity,

Figure 3 Indicators of human well-being and consumption rates are associated with monetary wealth. Wealthier nations have higher access to safe drinking water (a), lower child mortality rates (b), lower fractions of their populations undernourished (c), and lower rates of tuberculosis (d), an indication of disease risk. Wealthier nations also have lower fertility rates (e) and higher life expectancy (f), and higher literacy rates (g), an indication of demographic transitions. At the same time, consumption rates of energy (per capita) (h) and emissions of CO₂ (i) increase with wealth, indicating that gains in well-being come at a cost for the global environment. Data from the World Bank.

incentivization, greed, or negligence, governments and extractive industries often prioritize short-term economic gains above long-term sustainability. Even where environmental protection policies exist, higher levels of government may have little capacity to enforce them, and the potential economic gains from destructive exploitation negate incentives to attempt enforcement.

Such biodiversity loss can reinforce and increase poverty. When natural capital is converted into financial or manufactured capital, social, and political inequities often contribute to outcomes of increased poverty. Poor people living in proximity to biodiverse areas tend to accrue relatively fewer benefits, and often bear a greater burden of costs, from commercial resource exploitation. Poor people are disempowered politically, economically, and in some cases face cultural prejudice. As a result, they tend to receive the minimum compensation that larger polities can feasibly offer, ranging from forced land appropriation and resettlement, to conversion to an industrial wage labor force with reduced local authority and autonomy.

Local people also lose ecosystem services, such as wild and semiwild food sources, soil erosion control, water purification and recharge, pollinator services, and cultural values associated with biodiverse areas. Since poor rural populations rely more directly on those services, their loss exacerbates the challenges of poverty and decreases options for improving livelihoods. The poor become even poorer as they try to cope with land loss, meager wages, and the disappearance of the safety net of ecosystem services. Under such pressures, poor people must often resort to destructive resource use themselves in order to survive. Biodiversity loss and increased poverty are therefore both linked to social inequity in economic development. Certain development sectors, such as oil extraction in Africa and Latin America, forest conversion for soy production in Amazonia, and timber extraction in southeast Asia, have come to epitomize these dynamics.

International trade, global markets, and aid relations profoundly influence development trajectories in biodiverse regions. Many developed nations place higher political priority on environmental protection within their own territories, with the result that wealthier nations now import huge proportions of natural resources from developing countries. When donor aid is coupled to restructuring developing economies to prioritize exports, inequities at an international scale can disempower developing countries to conserve natural resources. This model of economic development is meant to increase wealth for developing countries. However, due to weak governance capacity, corruption, and pre-existing inequities within those countries, they can instead lead to greater wealth inequality and create poverty traps for the most vulnerable segments of society. The enticement of quick profits for countries in dire financial straits may generate perverse incentives for governments to tolerate or even prioritize practices that threaten biodiversity and perpetuate poverty. Coupled political inequities, between developed and developing countries, as well as within countries, can derail efforts for sustainable development and biodiversity conservation.

These outcomes of global trade are becoming more widely acknowledged. In response, developing countries are demanding more attention – and compensation – be paid for

the environmental burdens relegated to the developing world (Roberts and Parks, 2009). This is spurring an important current trend in sustainable development – to dismantle perverse incentives and create local, equitable economic benefits for maintaining biodiversity. Formulating win-win situations is feasible in theory, yet is difficult to achieve in practice. There are now hundreds of thousands of coupled conservation-poverty alleviation projects worldwide, which vary in their relative emphasis on conservation or poverty reduction, and in their strategies for overcoming inequities and perverse incentives (Adams *et al.*, 2004).

There are successful and failed examples in every kind of project linking biodiversity conservation and poverty alleviation: community based natural resource management, integrated conservation and development programs, payments for ecosystem services, sustainable biodiversity utilization, and the recently burgeoning enterprise of cash payments for intact ecosystems for carbon dioxide sequestration (so-called REDD, Reducing Emissions for Deforestation and Forest Degradation, programs). Given the case-specificity in every project, there is consensus on only a few common attributes of projects that yield greater successes. In general, successful programs are carefully designed to account for the specific nature of linkages and feedbacks between poverty and biodiversity in any given case. And equity is recurrently important. Conservation-poverty initiatives require collective action and regulation. If the governance and benefits are not perceived as equitable and legitimate, there tends to be a breakdown of trust, cooperation, and compliance, and project failure ensues (Ostrom, 1990).

Conservation-poverty programs also vary in their approaches to evaluate changes in human well-being and poverty reduction. The inclusive wealth framework is proposed to integrate the values of biodiversity as well as other forms of wealth, into an aggregate assessment of well-being. It is important to note, however, that in the context of assessing poverty reduction, the framework has limitations. As noted, sociopolitical and economic inequality are major drivers of biodiversity loss and persistence of poverty. Inclusive wealth is based on aggregate summations for a given economic unit, and currently does not account for inequities that exist within that unit. Incorporating metrics of economic inequality, such as the Gini coefficient, would add consideration of the status of the poorest as an additional factor in gauging societal well-being. It would also address the concern that empirically, economic inequality is a strong predictor of biodiversity loss (Mikkelsen *et al.*, 2007; Holland *et al.*, 2009).

Although there is much to debate and development in the study of biodiversity, poverty, and equity, there are likewise some key common trends that are critical to understanding the challenge of sustaining biodiversity. Biodiversity loss is largely driven by grossly disproportionate consumption in wealthy nations and in urban environments, and the resource exploitation and land conversion in developing countries necessary to support that consumption. There is geographic collocation of poor people and areas of high biodiversity, and those are also the regions where biodiversity loss is most rapid. The dynamics of biodiversity loss and poverty feedback on one another, which creates both situations of entrenched poverty as well as opportunities to potentially engineer win-win situations. Around the world, there are a panoply of efforts to achieve such

win-win outcomes, yet there is weak consensus as to the best ways to do so, or how to evaluate success. Environmental economics, political ecology, sustainability science, and conservation biology are among the host of academic disciplines striving to generate knowledge that can facilitate efforts to simultaneously sustain biodiversity and ecosystem services while alleviating poverty.

Diversity, Resilience, and Sustainability

Evaluating natural capital assets and their likely responses to decreases in resource use and consumption within the inclusive wealth framework are complicated by the fact that Earth system may not respond to change in easily predicted ways. A fundamental question that emerges is how stable are ecosystems and Earth systems in response to perturbation. Ecologists have long been interested in the temporal stability of structure and function of ecosystems, but have defined stability in two distinct ways. The first, termed engineering resilience by Gunderson (2000) defines resistance in terms of the sensitivity of ecosystems to disturbance (i.e., the magnitude of change in response to disturbance of some size) and resilience as the rapidity with which the system recovers to its predisturbance state. In many though by no means all cases (see article from Quijas and Balvanera, *Links between biodiversity and ecosystem services*), more diverse ecological communities are both less sensitive to change, and recover more rapidly to predisturbance values. Ecosystems that are more stable by these metrics might allow for ecosystem services to be obtained with greater regularity and predictability, and thus be of greater value. The shortcoming of studies based on resistance and engineering resilience (sensu Gunderson) is the presumption that ecosystems have a single equilibrium to which they ultimately return. The growing evidence that many ecosystems have more than one equilibrium (i.e., they possess alternative stable states) has more profound implications for relationships between diversity and sustainability.

The notion that ecosystems may shift abruptly between alternative stable states arose first from theoretical models but has since been demonstrated rigorously in natural systems. Some of the most convincing examples of such 'critical transitions' are found in shallow temperate lakes, which can switch rapidly from an oligotrophic clear water system to a eutrophic pea-green soup after nutrient additions pass a threshold (or 'tipping point') (Scheffer *et al.*, 2001). Importantly, reversing such a transition is extremely difficult, because positive feedbacks are reoriented to favor the new equilibrium. Another prominent example of such ecosystem behavior is the transition between woodlands and grasslands in arid and semiarid regions. Feedbacks among fire, herbivory, and the ability of plants to capture runoff all influence such landscapes. The same concepts of feedbacks, thresholds, and critical transitions have been applied to the apparently sudden collapse of human societies such as those in Central America, Easter Island, and elsewhere, generally due to collapse of environmental conditions. The existence of thresholds at the ecosystem scale also raises the notion that there may be planetary boundaries for critical factors, such as ocean acidification levels, atmospheric CO₂ concentrations, temperatures, species extinction levels,

and so forth, beyond which Earth systems may switch into alternative states unfavorable to human well-being (Rockström *et al.*, 2010).

The capacity of an ecosystem to absorb external shocks without undergoing such transitions between stable states has been termed 'ecological resilience,' which is the second way ecologists have measured stability. A resilient system, like a ball in a cup, will return to its original equilibrium except in cases of severe disturbance. In a system with low resilience, only a small disturbance may be needed to move past the lip of the cup (the 'basin of attraction') and into another state. Human activities and other external drivers can reduce resilience and increase the probability of state shifts by weakening the interactions that reinforce the original state. Management of ecosystems with alternative stable states requires managing for resilience.

The concept of alternative stable states is important to the integration of biodiversity and sustainability in several respects: First, at the local and global scale, biodiversity may itself be subject to catastrophic declines as the human influences on ecosystems intensify. Rather than a linear decline with resource use (Figure 4(a)), biodiversity may exhibit threshold responses where minor stressors have little or no impact on biodiversity, but major stressors lead to severe losses (Figure 4(b)). In other words, there is no guarantee that diversity responds in a smooth fashion to environmental pressures – in fact, most evidence points to the contrary. The ongoing mass extinction associated with humans may represent the crossing of such a threshold. At the global scale, loss of species diversity is effectively permanent and irreversible, due to the contingent nature of evolutionary processes and the sheer length of time required for new species to evolve. But even at the local scale, loss of foundation species may effectively prevent reestablishment of original diversity levels after removal of stressors – meaning that biodiversity may exhibit alternative stable states within individual ecosystems (Figure 4(c)).

The response of ecosystem processes (and thus ecosystem service provision) to biodiversity can also be nonlinear. Rather than linear decreases (Figure 4(d)), relationships between species diversity and ecosystem functions such as productivity exhibit little change initially, followed by increasing large declines at low species number (Figure 4(e); Cardinale *et al.*, 2011). In general, such relationships reflect redundancy among species' functional roles within ecosystems. How often feedbacks between ecosystem function and biodiversity are strong enough to generate alternative stable states (Figure 4(f)) is unknown.

Whether considering the response of biodiversity to environmental change, or the response of ecosystem services to biodiversity, nonlinear relationships have important implications for sustainability. Obtaining ecosystem services generally requires human institutions and infrastructure tailored for that purpose. Thus transitions to alternative states often incur significant costs due to the loss of services, even if the potential services from the new state are equal to those of the old. The risk of such losses is magnified by the fact that the location of thresholds and the potential loss of ecosystem services associated with a state transition are often difficult to determine ahead of time (Scheffer *et al.*, 2009). Global measures of sustainability such as inclusive wealth must

Figure 4 Potential relationships between human resource use and biodiversity (top row), and between biodiversity and ecosystem service provision (bottom row). Panels (a), (b), and (c) show linear, threshold, and hysteresis responses, respectively, of biodiversity to human resource use. Panels (d), (e), and (f) show linear, threshold, and hysteresis responses, respectively, of ecosystem service provision to biodiversity. Although the rate and costs of biodiversity loss are often assumed to be linear (a, d), some evidence suggests that these relationships exhibit sharp breaks at some level of human resource use (b) or biodiversity (e). A third possibility is that these relationships have alternative states (c, f), so that loss of biodiversity or the services that depend on them may not recover even when the underlying stressor (resource use or biodiversity loss) is ameliorated. Note that it would be possible for these relationships to exhibit one form when considered globally, and others when considered at the scale of individual ecosystems.

account for such risks if they are to guide or inform a sustainability transition.

One important implication of the inclusive wealth framework is that of intergenerational equity – the needs of the present balanced against those of future generations. Threshold relationships between biodiversity and ecosystem services (and among many other components of ecological systems) exacerbate the tension between maximizing current provision of ecosystem services and maintaining the capacity of ecosystem to provide services indefinitely, particularly when the potential for alternative states is considered. Available evidence suggests that maintaining diverse ecological communities is an important component of managing for resilient ecosystems and ensuring the future provision of ecosystem services.

Trends

Biodiversity Trends – The *Millennium Ecosystem Assessment* (2005) reports that extinction rates are 100 to almost 1000 times the background level of extinction based on the fossil record. Two thirds of the world's ecosystem services that depend on biodiversity are declining. These alarming trends led scientists to consider the current epoch of humanity the 'Sixth Extinction' (Leakey and Lewin, 1995). The largest driver of biodiversity loss is habitat change. On land, such changes occur through land use changes. Both globally and particularly in heavily indebted poor countries, conversion of land to agriculture (Figure 5(e)) has been on the rise in the last half century. Such trends occurred much earlier in many wealthier regions of the globe. Land conversions and land degradation

also degrade or destroy ecosystems and the services they provide to humans. Increasing need for fuelwood and land for agriculture, together with industrial logging, have resulted in global losses of forest at a rate of 16 million hectares per year during the 1990s. World deforestation, mainly the conversion of tropical forests to agricultural land, has decreased over the past decade (2000–2010) to approximately 13 million hectares of forests per year but continues at an alarmingly high rate in many countries (Global Forest Resources Assessment, 2010).

In coastal and ocean ecosystems, habitat change is driven by loss of coral reefs through ocean acidification, pollution, climate change, species invasions, overexploitation, and damage to sea floors due to trawling. In coastal ecosystems, Worm *et al.* (2006) report dramatic declines in populations of ecologically and economically important species: In fishery taxa that have maintained viable population sizes over the last 1000 years, 40% have collapsed (their populations have dropped below 10% of their maximum population size) since 1800. More than half of the world's coral reefs face changes in species composition, obliteration, and other major ecosystem effects. In open ocean ecosystems, the situation is even more dire: 80% of fish and invertebrate taxa in our global fisheries have collapsed in the last 50 years. These collapses have resulted in major losses of ecosystem services (fisheries, nursery habitat, and filter function) and with concomitant increases in risks (such as beach closures, harmful algal blooms, fish kills, oxygen depletion, coastal flooding, and species invasions).

Covering less than 1% of the Earth's surface, freshwater ecosystems have lost the largest proportion of species and habitat when compared with other ecosystems on land or with the oceans. Physical modification or water withdrawal from

Figure 5 Global trends in total and per capita energy use and land area for agriculture. (a) Total energy use in kt of oil equivalents for the World, high income nations and low income nations since 1960. High income and World totals continue to rise, whereas low income totals remain very low. (b) Per capita energy consumption has increased fairly steadily in high income nations since 1960 with a slight down-turn in recent years. (c) Fossil fuels still comprise the vast majority of energy consumption in the world, particularly in high income nations. In low income nations, fossil fuel energy use as a percentage of total energy use is much lower. Alternative energy sources, such as wind, solar, and nuclear remain very low percentages of total energy use throughout the world. (d) Electricity use per capita continues to increase steadily in high income nations but is stable in low income nations and for the World. (e) Land area for agriculture as a percentage of total land area has remained fairly stable in high income nations; it continues to increase in low income nations, and it is steadily increasing in heavily indebted poor countries, surpassing that of high income nations. (f) Air transport in terms of passengers carried an indicator of energy use and consumption that is afforded only by the wealthy, has grown steadily since 1970. This trend is driven largely by high income nations. Low income nations show very low and near constant levels. Data from the World Bank.

rivers, continuing overfishing, dam building and river development, and contamination have driven species losses and will continue to place greater threats on freshwater ecosystems. Many estuaries and bays have also deteriorated because of activities associated with land development and fishing pressure, undermining ecosystem services. All the habitat transformations have profound impacts on human well-being. Biodiversity losses affect the livelihood of local communities that depend on diverse ecosystems for food, tourism, and ecosystem stability.

Future projections of species extinction rates based on habitat change current population status of threatened or endangered species indicate that extinction rates will continue to rise to ten times their current rates (MEA, 2005), although the methods for generating such predictions are difficult

(He and Hubbell, 2011). Measuring and monitoring for biodiversity loss presents a major challenge given that possibly >85% of species on land and >90% in the ocean have still not been identified or described (Mora *et al.*, 2011).

Trends in health, consumption, and communication – At the same time that biodiversity indicators show increasing cause for alarm in our ability to manage for sustainability, indicators of human well-being continue to show positive trends (Figure 1(c) and 1(e)). But these benefits to human well-being have come at the cost of consumption of non-renewable resources (Figure 5(a)–(d)), homogenization of the biota, emission of climate altering greenhouse gases (Figure 6(a) and 6(b)), and pollutants to human health (Figure 6(c) and 6(d)). Inequities in the distributions of costs and benefits are apparent, as discussed in section Diversity,

Resilience, and Sustainability. Indicators such as disease incidence, literacy rate, safe drinking water access, and life expectancy indicate that wealthier nations have higher material well-being in terms of health, education, and access to basic resources (Figure 3). Wealthy nations have high per capita energy consumption rates and CO₂ emissions rates (Figure 3(h) and (i)). As such, wealthy nations appear to be reaping the benefits of consumption but the costs of this consumption is paid for globally. CO₂ emissions per capita have begun to level off in wealthy nations; globally, however, yearly emissions continue to increase as a result of population growth and consumption in fast developing countries. In the past 50 years, total annual nitrous oxide pollution has remained relative constant and particulate matter has markedly declined (Figure 6(c) and (d)). Electricity use per capita and total energy use of high income countries continues to rise. Air travel in wealthy nations and globally has risen sharply.

At the same time, humans are increasingly connected and have the capacity to share ideas, cultural values, and transfer technology rapidly. The exponentially increasing trends in internet use and cell-phone use (Figure 7(a) and (b)) attest to the increasing global connectedness. The same global interconnectedness that creates pressures on biodiversity may also facilitate mechanisms such as REDD that provide incentives to address climate change while sustaining biodiversity.

Meeting human needs while preserving the Earth's life support systems for future generations will require a world-wide acceleration of today's halting progress in a transition toward sustainability. Whether humanity can take advantage of human capital, knowledge, and technological advances to develop processes and governing mechanisms to achieve sustainability will determine much about the fate of the Earth's biodiversity.

Figure 6 Pollution levels show contrasting trends. Although global CO₂ emissions have risen sharply (a), people in wealthy nations are largely responsible (a, c). Nitrous oxide emissions have stabilized (c) whereas particulate matter has decreased (d). Data from the World Bank.

Figure 7 Exponential increase in global cell phone subscriptions (a) and internet users (b) in recent decades provides an indication of the change in communication and access to information that human societies have undergone. Data from the World Bank.

Glossary

Biodiversity (BD) BD is defined by the Convention on Biological Diversity (CBD) as “the variability among living organisms from all sources, including, *inter alia*, terrestrial, marine, and other aquatic ecosystems and the ecological complexes of which they are part; this includes diversity within species, between species, and of ecosystems.”

Biosafety Biosafety is a term used to describe efforts to reduce and eliminate the potential risks resulting from biotechnology and its products. For the purposes of the Biosafety Protocol of the CBD, this is based on the precautionary approach, whereby the lack of full scientific certainty should not be used as an excuse to postpone action when there is a threat of serious or irreversible damage.

Mainstreaming The persistence of BD, including threatened species that are not solely dependent on site-based action, require the sustainable management of landscape and seascape mosaics that include protected areas and a variety of other land and resource uses outside of these protected areas. Measures that help reduce the negative impacts that productive sectors exert on BD, particularly outside of protected areas and highlight the contribution of all components of BD to ecosystem functioning, economic development, and human well-being is often referred to as “BD mainstreaming.”

Payment for ecosystem services (PESs) The definition of “PESs” varies widely from narrow market-based definitions with emphasis on direct transactions between providers and beneficiaries (sometimes with specifications on the nature and conditions of the transaction between buyers and sellers) to broader schemes, where those who benefit from ecosystem services pay those who provide such services. Overall, PES for GEF has involved arrangements between buyers and sellers of environmental goods and services, where those who pay are fully aware of what they are paying for, and those who sell proactively and deliberately engage in resource use practices aimed at securing the provision of the services.

Protected area system “sustainability” The GEF defines a sustainable protected area system as one that: (1) has sufficient and predictable financial resources available,

including external funding, to support protected area management costs; (2) effectively protects ecologically viable representative samples of the country's ecosystems and provides adequate coverage of threatened species at a sufficient scale to ensure their long-term persistence; and (3) retains adequate individual and institutional capacity to manage protected areas such that they achieve their conservation objectives.

The Global Environment Facility (GEF) The GEF unites 182 member governments – in partnership with international institutions, nongovernmental organizations (NGOs), and the private sector – to address global environmental issues. As an independent financial organization, the GEF provides grants to developing countries and countries with economies in transition for projects related to BD, climate change, international waters, land degradation, the ozone layer, and persistent organic pollutants (POPs). These projects benefit the global environment linking local, national, and global environmental challenges and promoting sustainable livelihoods. The GEF partnership includes 10 agencies: the United Nations (UN) Development Program; the UN Environment Program; the World Bank; the UN Food and Agriculture Organization; the UN Industrial Development Organization; the African Development Bank; the Asian Development Bank; the European Bank for Reconstruction and Development; the Inter-American Development Bank; and the International Fund for Agricultural Development. Recently, the GEF Council has approved a pilot program to accredit national agencies for direct access to GEF resources, becoming a pioneer in this modality among multilateral funding mechanisms. The Scientific and Technical Advisory Panel provides technical and scientific advice on the GEF's policies and projects. The GEF serves as financial mechanism for the following conventions: CBD, UN Framework Convention on Climate Change, Stockholm Convention on POPs, and UN Convention to Combat Desertification. The GEF, although not linked formally to the Montreal Protocol on Substances That Deplete the Ozone Layer, supports implementation of the Protocol in countries with economies in transition.

Introduction to the GEF and GEF Support to Biodiversity Conservation: Background and Context

What is the Global Environment Facility?

The Global Environment Facility (GEF) was established in October 1991 as a \$1 billion pilot program of the World Bank

to assist in the protection of the global environment and to promote environmentally sustainable development. The GEF would provide new and additional grants and concessional funding to cover the “incremental” or additional costs associated with transforming a project with national benefits into one with global environmental benefits. The United Nations

(UN) Development Program, the UN Environment Program, and the World Bank were the three initial partners implementing GEF projects.

In 1992, at the Rio Earth Summit, the GEF was restructured and moved out of the World Bank system to become a permanent, separate institution. The decision to make the GEF an independent organization enhanced the involvement of developing countries in the decision-making process and in implementations of the projects. However, since 1992, the World Bank has served as the Trustee of the GEF Trust Fund and provided administrative services.

As part of the restructuring, the GEF was entrusted the financial mechanism for both the UN Convention on Biological Diversity (CBD) and the UN Framework Convention on Climate Change (UNFCCC). In partnership with the Montreal Protocol (MP) of the Vienna Convention on Ozone Layer Depleting Substances, the GEF started funding projects that enable the Russian Federation and nations in Eastern Europe and Central Asia to phase out their use of ozone-destroying chemicals.

The GEF subsequently was also selected to serve as a financial mechanism for two more international conventions: The Stockholm Convention on Persistent Organic Pollutants (POPs, 2001) and the UN Convention to Combat Desertification (UNCCD, 2003).

The GEF unites 182 member governments in partnership with international institutions, civil society, and the private sector. As the world's largest public financial organization dedicated to global environmental issues, the GEF provides grants to developing countries and countries with economies in transition for projects related to biodiversity (BD), climate change (CC), international waters, land degradation (LD), the ozone layer, and POPs. These projects link local, national, and global environmental challenges while promoting sustainable livelihoods.

Over its 20 year history, the GEF has directly invested \$9.5 billion, leveraging another \$42 billion toward more than 2700 projects in 165 countries. Through its Small Grants Program (SGP), the GEF has also made more than 12,000 small grants directly to NGOs and community organizations.

The GEF partnership includes 10 agencies: the UN Development Program, the UN Environment Program, the World Bank, the UN Food and Agriculture Organization, the UN Industrial Development Organization, the African Development Bank, the Asian Development Bank, the European Bank for Reconstruction and Development, the Inter-American Development Bank, and the International Fund for Agricultural Development. Recently, the GEF Council has approved a pilot program to accredit national agencies for direct access to GEF resources, becoming a pioneer in this modality among multilateral funding mechanisms. The Scientific and Technical Advisory Panel provides technical and scientific advice on the GEF's policies and projects.

The GEF also serves as financial mechanism for the following conventions:

- CBD
- UNFCCC
- Stockholm Convention on POPs
- UNCCD

- The GEF, although not linked formally to the MP on Substances That Deplete the Ozone Layer, supports implementation of the protocol in countries with economies in transition.

The GEF and the CBD

The CBD provides the global policy framework to address BD issues. The CBD also provides the guidance under which the GEF operates to assist countries in meeting their obligations under the Convention. In other words, the GEF is the financial instrument of the Convention and is the only binding multilateral agreement in this area, with 190 parties. The objectives of the CBD are defined in Article 1 as "...the conservation of biological diversity, the sustainable use of its components and the fair and equitable sharing of the benefits arising out of the utilization of genetic resources, including by appropriate access to genetic resources and by appropriate transfer of relevant technologies, taking into account all rights over those resources and to technologies, and by appropriate funding."

The relationship between the Conference of the Parties (COPs) of the CBD and the GEF is ruled by a memorandum of understanding (*Convention on Biological Diversity, 1992*). In accordance with Article 21 of the Convention, the COP determines policy, strategy, program priorities, and eligibility criteria for access to and utilization of financial resources available through the financial mechanism, including monitoring and evaluation. In translating the COP guidance to operational policy for implementation, the Secretariat, in consultation with the GEF Agencies, assesses how the guidance can best be implemented. The GEF defines new or strengthened strategic objectives and approaches, modalities, operational criteria, procedures, and any other process needed and presents this for Council approval. In applying COP guidance in project operations, the GEF and its implementing agencies support country-driven, national priority projects and programs endorsed by relevant GEF focal points (i.e., full- and medium-sized projects, SGP, and enabling activities).

GEF Funding for BD

The level of investment in national BD projects that would be warranted by the global benefits of those projects is frequently greater than the investment warranted by local development or environmental priorities. The GEF provides grants in support of national projects to cover the difference – the incremental cost of achieving the desired level of global benefits generated by BD conservation and sustainable use.

The GEF's BD portfolio has been the largest focal area portfolio in terms of grant money awarded since the facility began operations and has accounted for approximately 31% of the total GEF grants to developing countries and those with economies in transition. Since 1991, the GEF has provided about \$3.1 billion in grants and leveraged about \$8.3 billion in cofinancing to support approximately 990 projects that addressed the loss of globally significant BD in more than 155 countries (*Figure 1*).

Figure 1 GEF Biodiversity Investments FY 1991–2010 (US\$ billion). The GEF's biodiversity portfolio has been the largest focal area portfolio in terms of grant money awarded since the Facility began operations.

System for Transparent Allocation of Resources

The GEF allocates resources in an indicative way to GEF-eligible countries during a replenishment period through the System for Transparent Allocation of Resources (STAR). It was developed during 2009–2010 to upgrade the Resource Allocation Framework (RAF), which was the former GEF resource allocation system used in the fourth replenishment period of the GEF (GEF-4).

In the fifth replenishment period of the GEF (GEF-5), the STAR covers three focal areas: BD, CC, and LD. Other focal areas and programs may be covered by the STAR in the future GEF replenishment periods.

The main benefits of the STAR for eligible countries are predictability of funding and flexibility in programming. This will enhance planning and contribute to country ownership of GEF projects and programs.

The funding envelope that a given country can access during a replenishment period is called "indicative allocation." Indicative allocations are calculated based on a combination of the GEF benefits index (GBI), the GEF performance index (GPI), and a social and economic index based on the Gross Domestic Product (GDPI).

The GBI represents the global environmental benefits that can be generated for each focal area in a specific country. The GPI is specific to a country and is the same across all focal areas. The GDPI is a new design feature of the STAR. The rationale to have the new index in the STAR is that poorer countries need additional funding to build the capacity that is required to ensure the success of GEF project development and implementation. The GDPI is the same for all focal areas in a country.

A GBI in the STAR is an index to measure GEF's investment benefits in a specific focal area in a country. In the STAR, there are three GBIs: GBIBD, GBICC, and GBILD. They are directly related to environmental indicators for three focal areas: BD, CC, and LD. The GBIs in a focal area represent a country's relative share of GEF potential benefits that can be generated by a fixed amount of resource input in the focal area. The higher the GBI in a focal area, the higher are the investment benefits to be generated.

The GPI in the STAR is an index to provide a relative ranking of eligible countries' performance and capacity to

deliver potential global environmental benefits. The GPI is the same across all focal areas in a country. The calculation of the GPI is based on a country's past and current performance in project development and implementation, and on the quality of each country's policies and institutions. The GPI therefore provides a proxy measure of each country's capacity to successfully implement GEF programs and projects to deliver the potential global environmental benefits identified by the GBI.

The GDPI is designed so as to increase the allocation of countries with low GDP per capita, decrease the allocation of countries with higher GDP per capita, and keep the allocations with middle GDP per capita unchanged. The higher the GDP per capita, the larger impact the GDPI will have.

The calculation of indicative country allocation scores for BD under the STAR is based on three indices: (1) the GBIBD, (2) the GPI, and (3) the GDPI.

The same GBIBD data were used in the RAF and in the STAR. In the RAF, the GBIBD score consisted of two components: (1) terrestrial score (80%) and (2) marine score (20%). In the STAR, the weights were slightly modified – terrestrial (75%) and marine score (25%).

For BD, the "benefits index" is built utilizing the updated GEF-4 benefits index, but with an increased weight for the marine component from 20% to 25%. The GBI makes maximum use of the available, scientifically reliable information for a cross-country assessment of terrestrial and marine BD. The GBI reflects the complex, highly uneven distribution of species and threats to them across the ecosystems of the world, both within and across countries. In terrestrial BD, the GBI accounts for ecoregion representation, species representation, threatened species, and threatened ecoregions. In marine BD, it accounts for species representation.

Evolution of the GEF BD Strategy: From GEF Inception to the Present

GEF Operational Strategy and GEF Operational Programs

Until the formulation of GEF's first targeted BD strategy for implementation during GEF-3 (2003–2006), the GEF BD portfolio was built on the GEF Operational Strategy and Operational Programs, as well as the guidance provided to GEF from the COP. The GEF Operational Strategy defines the 10 operational principles for development and implementation of the GEF's work program. The GEF Operational Programs in BD were built on the general Operational Strategy and defined, by ecosystem type, specific criteria by which the GEF projects were further characterized and evaluated. Earlier implementation of the GEF BD program emphasized eligibility based on fit with one or more of the five BD operational programs: arid and semiarid ecosystems, coastal–marine and freshwater ecosystems, forest ecosystems, mountain ecosystems, and agro-BD.

GEF's BD Strategy

The Formulation of the First BD Strategy for GEF-3

In response to the two external evaluations undertaken by the BD program, the Second Program Study of the GEF

Biodiversity Program and the Second Overall Performance Study, the GEF developed a strategy for GEF-3 to focus the GEF's investment strategy on four priorities:

1. catalyzing the sustainability of protected areas,
2. mainstreaming BD in the production of landscapes/seascapes and sectors,
3. capacity building for the implementation of the UN CBD Cartagena Protocol on Biosafety (CPB), and
4. generation and dissemination of best practices for addressing current and emerging BD issues.

The main purpose for sharpening the investment focus of GEF resources was to apply scarce GEF resources in a manner that most effectively catalyzes actions to maximize global environmental benefits. The priorities for GEF-3 internalized the most pertinent recommendations that had emerged from the evaluation exercises and provided a framework for the entire portfolio. The GEF developed its first targeted BD strategy in GEF-3 to complement and further focus its operational programs and to respond to evaluation findings (*Biodiversity Program Study, 2004*).

The GEF-3 strategy incorporated principles to achieve lasting BD conservation and sustainable use and thereby: (1) placed greater emphasis on sustainability of results and the potential for replication; (2) moved beyond a project-based emphasis to strategic approaches that strengthened country enabling environments (policy and regulatory frameworks, institutional capacity building, science and information, and awareness); (3) mainstreamed BD conservation and sustainable use in the wider economic development context; and (4) increased support for sustainable use and benefit sharing. The changes implemented in the GEF-3 strategy formed the foundation on which subsequent GEF strategies have been built. The strategy for each new phase has maintained continuity with these basic tenets of sustainability while incorporating new findings on good practice in BD conservation and sustainable use.

BD Strategy for GEF-4 and GEF-5

The GEF revised its strategy for GEF-4 (2007–2010) (GEF BD Strategy, GEF-4, and GEF-5) based on the implementation experience gained during GEF-3 and in response to evolving thinking in the conservation community about the drivers of BD loss. The GEF-funded Millennium Ecosystem Assessment identified the most important direct drivers of BD loss and degradation of ecosystem goods and services as being habitat change, CC, invasive alien species, overexploitation, and pollution (*Millennium Ecosystem Assessment (2005)*). These drivers are influenced by a series of indirect drivers of change, including demographics, global economic trends, governance, institutions and legal frameworks, science and technology, and cultural and religious values. The BD strategy in GEF-4 addressed a subset of the direct and indirect drivers of BD loss and focuses on the highest leverage opportunities for the GEF to contribute to sustainable BD conservation.

To achieve the goals of the GEF-4 BD strategy, four complementary and mutually reinforcing objectives were implemented: (1) improving the sustainability of protected area systems, the most predominant and dedicated land use

globally for BD conservation; (2) mainstreaming BD conservation and sustainable use into production sectors that impact BD; (3) safeguarding BD by building country capacity to implement the CPB and prevention, control, and management of invasive alien species; and (4) capacity building to support the implementation of the Bonn Guidelines on access to genetic resources and benefit sharing. Underpinning these responses, GEF supported institutional capacity building and the development of the appropriate policy frameworks to ensure sustainable BD conservation.

The GEF-4 strategy formally replaced the previous structure of operational programs and balanced the need for continuity in the investment strategy, while focusing more explicitly on specific interventions for sustaining conservation over the long term.

The GEF BD strategy is consistent with the integrated approaches to BD conservation and sustainable use promoted by the ecosystem approach, the primary framework for action under the CBD. Together, these strategic objectives will make a substantial contribution to implementing most of the Millennium Development Goals, particularly environmental sustainability and poverty reduction, while meeting the priorities identified by the COP of the CBD.

The GEF-5 (2010–2014) strategy maintains coherence with the GEF-4 strategy, while proposing refinements to the strategy's objectives based on COP-9 guidance, advances in conservation practice, and advice from the GEF's Scientific and Technical Advisory Panel. The ninth meeting of the COPs of the CBD acknowledged that the GEF-4 strategy served as a useful starting point for the GEF-5 strategy and requested GEF to build on it for the fifth replenishment based on the 4-year framework of program priorities developed by COP-9.

The goal of the BD focal area is the conservation and sustainable use of BD and the maintenance of ecosystem goods and services. To achieve this goal, the strategy encompasses five objectives:

1. improve the sustainability of protected area systems,
2. mainstream BD conservation and sustainable use into production landscapes/seascapes and sectors,
3. build capacity to implement the CPB,
4. build capacity on access to genetic resources and benefit sharing, and
5. integrate CBD obligations into national planning processes through enabling activities.

GEF Financing of Sustainable Forest Management and its Contribution to BD Conservation

Forests cover almost 4 billion ha, or 30%, of the world's total land area. They are found virtually everywhere, from the boreal forest to the humid tropics. The broad variety of forest types – in tropical, subtropical, Mediterranean, temperate, and boreal regions – together account for two-thirds of all terrestrial ecoregions. They provide a wide range of environmental services, including BD conservation, water supply, carbon sequestration, flood control, and protection against soil erosion and desertification.

Equally important, forest ecosystems contain at least an estimated 80% of the Earth's BD. Tropical forests are

particularly rich in species. Although covering only approximately 10% of the total terrestrial surface, they correspond to approximately 50% of the area covered by world's forests and are home to considerably more than 60% of all terrestrial and freshwater BD.

The UNFCCC, the CBD, and the UNCCD all emphasize the importance of the conservation, sustainable use, and management of forests in achieving their respective Convention objectives. As operating entity of the financial mechanisms for all three Conventions, the GEF has since 1991 supported more than 300 projects and programs that focus on various actions dealing with forest conservation and management in developing countries. During the same period, the GEF has allocated approximately US\$1.6 billion to forest initiatives, supplemented by more than US\$5.0 billion in cofinancing. GEF has continuously increased its financial flows for forest-related activities throughout its successive replenishment periods.

Drawing on guidance from the related conventions, from its eligibility criteria, and from associated strategic programs, the GEF has funded projects that can be broadly classified into three categories:

1. forest conservation (primarily protected areas and buffer zones),
2. sustainable use of forests (forest production landscapes), and
3. sustainable forest management (SFM) (addressing forests and trees in the wider landscape).

Historically, most of the GEF's investments were dedicated to forest conservation. However, investments in the latter two categories have increased considerably with the introduction of a dedicated program in SFM.

Until 2006, GEF supported forest projects drawing from the focal areas of BD and LD. In response to the growing international recognition of the role of forests in delivering global benefits across a variety of themes, in 2007, the GEF Council approved the broadening of the GEF's efforts in the field of SFM. Adopting the framework of the UN Forum on Forests, the GEF considers SFM "a dynamic and evolving concept that aims to maintain and enhance the economic, social, and environmental value of all types of forests, for the benefit of present and future generations." The inclusion of Land Use, Land-Use Change and Forestry (LULUCF) into the climate change strategy enabled support to projects and programs that deliver global benefits across all three GEF focal areas that are directly relevant to forests: BD, CC, and LD.

Through its pilot SFM Program in GEF-4 (2007–2010), the GEF took early action in the Reducing Emissions from Deforestation and Forest Degradation (REDD+) and LULUCF arenas by providing resources for pilot projects focusing on cross-sectoral cooperation. In the current funding cycle GEF-5 (2010–2014) and in line with the Copenhagen Accord that calls for "...substantial finance to reduce emissions from deforestation and forest degradation..." the GEF is expanding its support to actions reducing deforestation and will provide up to \$1 billion for the implementation of a dedicated SFM/REDD+ Program throughout the period 2010–2014, during which the GEF will manage a separate

\$250 million funding envelope for SFM/REDD+. This envelope operates as an incentive mechanism for developing countries to invest up to \$750 million of their allocations from BD, CC, and LD for more comprehensive SFM/REDD+ projects and programs. Altogether, the GEF will thus make up to \$1 billion for SFM/REDD+ funding available throughout the course of GEF-5. This investment is expected to leverage substantial additional funding from external sources.

Monitoring the GEF BD Portfolio

Monitoring Results at the Portfolio Level

The independent GEF Evaluation Office develops the policy, related guidelines, and administrative procedures for monitoring and evaluation in the GEF. The policy and guidelines help project managers and Agency and GEF Secretariat staff plan and conduct monitoring and evaluation. The GEF Monitoring and Evaluation Policy provides norms and standards for the GEF Secretariat and the GEF Evaluation Office. The Policy explains the concept, role, and use of monitoring and evaluation within the GEF; establishes minimum requirements for how projects should be monitored and evaluated in line with international standards; and assigns roles and responsibilities for these tasks. The GEF Agencies plan and implement their project monitoring and evaluation, in line with their own systems and procedures and based on these minimum requirements.

The GEF introduced BD "tracking tools" in GEF-3 to measure progress in achieving the outputs and outcomes established at the portfolio level for GEF-3 in the BD focal area. (GEF website, <http://www.thegef.org>). These tools have evolved with each successive phase of the GEF based on experience applying the tools and changes in GEF's portfolio results framework.

The tracking tools are applied three times during the life of the project: at project initiation to establish a baseline, then at project midterm, and at project completion. Project outcomes from each GEF phase cohort are aggregated for analysis of directional trends and patterns at a portfolio-wide level to inform the development of future GEF strategies and to report to the GEF Council on portfolio-level performance in the BD focal area as the projects are completed and evaluations conducted.

Learning at the Portfolio Level

The GEF Results-Based Management (RBM) framework and approach includes an emphasis on portfolio monitoring and learning by placing particular attention on using monitoring information for accountability, internal management, learning, and knowledge management.

In support of the GEF RBM and based on a review of evaluations of the BD focal area, a select number of learning objectives were identified for the BD focal area and these were included in the GEF-5 BD strategy to be implemented and lead by the GEF Secretariat in collaboration with the GEF Agencies.

The three learning objectives share in common a dual-fold purpose, in that the results will contribute to strengthening

GEF's capacity to deliver on its own mandate and the broader global public good of enhanced knowledge to catalyze change in BD conservation practice. Three learning objectives are proposed for implementation in GEF-5 and include:

1. Learning Objective One: "Enhancing Impacts and Outcomes through Improved Understanding of Protected Area Management Effectiveness." The learning objective is to better correlate protected area management effectiveness as recorded by a scorecard (Management Effectiveness Tracking Tool (METT)) to the successful conservation and sustainable use of BD within a protected area. This learning objective will be accomplished through a series of country case studies and field visits to select countries that have been applying the METT over an extended period of time in their protected area system and that are also collecting quantitative data on the status of BD and protection within the system.
2. Learning Objective Two: "Enhancing Social Impacts through Improved Understanding of the Causal Relationships between Protected Area Management and Local Community Welfare." This learning objective seeks to answer the following question, "What has been the impact of protected areas on human welfare?" This learning objective will be accomplished through a systematic review of the literature as well as complementary case studies when these are designed to focus on elucidating potential causal relationships.
3. Learning Objective Three: "Enhancing Impacts through Improved Understanding of the Causal Relationships between Popular Mainstreaming Approaches and Conservation Outcomes." As a leader in supporting innovative incentive-based and information-based mainstreaming approaches, the GEF has observed an increase in the number of funded projects using certification, Payment for ecosystem services (PESs), and ecosystem service valuation. Thus, the GEF has an opportunity to contribute the evidence base of these approaches by supporting work to answer the following question, "How do certification, PES, and transfers of information about the distribution and values of ecosystem services affect conservation and sustainable use outcomes, and in what circumstances are they likely to be most effective?" This learning objective will be accomplished primarily through the support of prospective experimental and *quasi*-experimental project designs. When feasible, quantitative retrospective studies in programs that have received GEF funding will also be supported.

The GEF network of agencies, partner government, and nongovernment executing agencies and country-based staff will be the main users of the findings derived from the portfolio monitoring and learning review process.

Given the extensive investment that the GEF has made in protected areas over the course of its existence (\$1.89 billion of GEF resources, which supported 2302 protected areas spanning 634 million ha and 700 globally threatened species), priority has been placed on first implementing learning objective one, "Enhancing Impacts and Outcomes through Improved Understanding of Protected Area Management Effectiveness," through five country case studies as a priority for the first 2 years of GEF-5. The first learning mission was

undertaken in Zambia in 2010 and the full report can be found at: <http://www.thegef.org>. The report represents a new era of portfolio monitoring and learning at the GEF, where the portfolio is used as a source for developing the evidence base for effective conservation investments.

Looking Ahead: What is Next for GEF

A New GEF: Seeking BD Impacts Commensurate with the Scale of the Threats

To continue to fulfill its function as the financial mechanism of the CBD, the GEF must evolve and be strengthened. The emphasis on BD as an individual focal area will remain at GEF, not only to highlight the specificities of dealing with an irreplaceable global good whose value to society remains to be fully assessed but also to address the ways to deal with existing and emerging threats, as well as identify rapidly expanding opportunities to act strategically. GEF also needs to support larger programs composed of many complementary projects, which themselves could include resources from different GEF focal areas, adding to the BD-specific investments.

The reformed GEF created a Natural Resources Management team, breaking the silos that existed in the focal areas of BD, LD, and international waters. This structure allowed for strategic cross-fertilization to occur and enabled new multifocal area programs to emerge, such as the SFM/REDD + program. The other pioneering programs introduced during GEF-4 (e.g., Pacific Alliance for Sustainability and the China Biodiversity Partnership and Framework for Action, among others) have opened the opportunity to pool resources from BD, CC mitigation and CC adaptation, LD, and international waters into more integrated programmatic action plans tackling multiple issues and fostering synergy among a diverse set of interventions. Such a scale of action also promotes a higher degree of efficiency in the overall conservation investment.

Nothing can better illustrate this change in the scope of planned interventions, and in the ambition of delivering outcomes that are fundamental to BD but also result in multiple benefits, than GEF's SFM Strategy. Tropical forests, in addition to conserving global BD, sustaining rural livelihoods, and providing spiritual and cultural havens for local and remote populations, are also among the largest and most important providers of ecosystem services on Earth, fundamental to maintaining our planet's long-term health and stability. Tropical forests have now been identified as a significant part of the overall CO₂ emission reduction scheme, given that they are responsible for 20% of the current greenhouse gas emissions problem.

As the GEF gained experience through the implementation of its SFM program, it built the foundation for a more ambitious global forest initiative in GEF-5, incorporating more explicit CC mitigation objectives. Threats to forests and opportunities for their conservation and sustainable management arise from a variety of sectors. These include agriculture expansion, shifts in global commodity markets, infrastructure development, and energy. But, more importantly, the role of forests in the global carbon equation is solidifying in policy

Box 1**Key accomplishments of the GEF in biodiversity**

- The GEF biodiversity focal area program has provided approximately \$2.9 billion in grants and leveraged an additional \$8.2 billion in cofinancing to support 990 projects in more than 155 countries.
- The GEF is the largest funding mechanism for protected areas worldwide. GEF has invested in more than 2302 protected areas, covering more than 634 million ha, an area equivalent to Greenland and Mongolia put together. The GEF has provided more than \$2.9 billion to fund protected areas, leveraging an additional \$8.2 billion in cofinancing from project partners.
- The GEF leads the world in establishing financing mechanisms to sustainably finance and operate national protected areas systems in developing countries. It has supported more than 90 projects that involve conservation trust funds, PESs schemes, revolving funds, private sector and village funds, and other innovative financial mechanisms to provide steady, reliable funding for protected area management, and biodiversity conservation in developing countries.
- The GEF is recognized as a pioneer in supporting more than 40 conservation trust funds worldwide, investing more than \$300 million in total.
- GEF's PESs portfolio includes more than 42 projects with explicit PES components. Investments have been made in the development of national systems of PES, regional, or local schemes with investments from the private sector, and private-public partnerships.
- The GEF is recognized as the first provider of capacity building in the area of biosafety, where the GEF has invested more than \$115 million and leveraged more than \$113 million.
- The GEF has supported the development of National Biosafety Frameworks in 123 countries, contributing to a rapid ratification by countries of the CPB and has built the capacity for the countries' effective participation in the Biosafety Clearing House mechanism.
- The GEF has supported 71 countries to effectively implement their National Biosafety Frameworks and the CPB.
- The GEF has developed strong partnerships with civil society organizations, including NGOs and indigenous and local communities, through its biodiversity program. The GEF SGP has provided small grants to more than 6945 biodiversity projects proposed by NGOs and community-based organizations in 121 countries, with a total GEF funding of \$51 million. The Critical Ecosystem Partnership Fund is another GEF partnership mechanism, with a program budget of more than \$125 million, which has reached out to more than 1000 civil society organizations in 33 countries to help conserve the world's most important biodiversity hotspots. More recently, the GEF has partnered with the World Bank and the International Union for Conservation of Nature, together with the French Fonds Français pour l'Environnement Mondial and private sector partners, in the Save our Species (SOS) Initiative. SOS aims to become a significant provider of funding in support of the conservation of globally threatened species, as well as raising global awareness to the plight of biodiversity worldwide.

circles, and the GEF is now programmatically prepared to act swiftly in this arena. The effective implementation of the SFM strategy will thus require a more holistic, wide-reaching approach.

The imperative of dealing with CC has introduced a new reality to GEF's programs spanning BD outcomes. Although it is necessary to act in the short term, before important windows of opportunities to safeguard global BD close, it is no longer sufficient to solely address the most immediate BD conservation challenges. For example, pressing action must start to be complemented by long-term sustainability interventions to cope with the anticipated effects of CC. In some regions, entire protected area systems will need to be the focus of adaptation strategies, as species and communities adjust to a changing environment.

At the same time, the opportunities to combine multiple goals in natural resources management are growing. We now know how interdependent the objectives of combating desertification, introducing sustainable land management, and improving productive systems all are for successful BD conservation strategies to emerge.

The GEF must also continue to expand its efforts in building the capacity of institutions to act as effective stewards of their environmental goods. Capacity building is likely the most enduring of investments, but one whose results are felt mostly in the medium and long term.

In the long term, BD conservation must be mainstreamed into all development sectors. There is an emerging consensus among environmental economists that changes in BD affect the provision of ecosystem goods and services, particularly those on which rural communities depend most. Although the magnitude of this dependence is yet to be determined, most studies agree that BD conservation is a very worthwhile investment, in particular for BD-rich countries. The GEF is open to embrace these new challenges and opportunities, experimenting with large-scale projects, and programs on mainstreaming BD into productive landscapes **Box 1**.

Glossary

Conveyance The movement of water through an area. For example, by increasing the cross-sectional area available to convey floodwaters, floodplains can reduce flood stage.

Ecosystem-based adaptation Conservation and management of natural ecosystems such that they can provide services that help society adapt to perturbations from climate change.

Ecosystem service Products and processes generated by functioning ecosystems that economically benefit society.

Floodplain Low-lying land adjacent to a river and subject to periodic inundation from overflow from the river and other sources.

Flood-recession agriculture A pattern of agriculture in which crops are planted on floodplains as floodwaters recede. The growing plants benefit from several factors influenced by the flood, including moist soil, elevated water table, and freshly deposited soil and nutrients.

Hydrologic connectivity The ability for water to move between portions of a river system, such as between a river channel and floodplain surfaces.

Levee A structure built along rivers intended to contain floodwaters and prevent flooding of land behind the structure. Also referred to as “dikes.” Note that natural levees can form along rivers through geomorphic processes.

Nonstructural flood management Flood-risk management approaches that do not depend on controlling water with engineered structures. Examples include land-use planning, building codes, insurance, and use of the natural and beneficial functions of floodplains, including storage and conveyance of floodwater.

Residence time Hydrological residence time is the length of time that a given unit of water remains in a given place and thus reflects the exchange rate of water at that place. Residence time can be calculated in many ways. One simple method is by dividing the volume of the area of interest (e.g., floodplain site) by the flow rate.

Riparian forest Forests that grow adjacent to rivers and within floodplains, generally composed of trees tolerant of periodic flooding and riparian trees often require flooding to promote their regeneration.

Introduction

Floodplains are dynamic and productive ecosystems whose immense values are often overshadowed by losses of life and property during large flood events. Despite the attention generated by disasters, floodplains support rich ecosystems and provide critically important benefits to people in diverse ways. In some regions, periodic inundation of the floodplain is essential to the provision of benefits, such as those from fisheries or flood-recession agriculture, so named because planting occurs as the floodwaters recede. In other settings, floodplain benefits depend on disconnecting the river from the floodplain, such as through levees that protect flood-intolerant crops growing on rich alluvial soil. In this article, the authors review how maintaining or restoring floodplain connectivity can promote the full spectrum of floodplain benefits. While the benefits that require flooding are clearly enhanced by river–floodplain connectivity, the benefits that require the absence of flooding can also be enhanced through strategically located connections between rivers and floodplains as part of comprehensive flood-risk management. In other words, some designated locations are allowed to flood in order to reduce flood risk for other areas. In this way, floodplains act as “green infrastructure” complementing the

services provided by engineered infrastructure, such as dams and levees, for managing flood risks.

In this article, the authors review floodplain processes and how connectivity between the river and floodplain drives productivity, diversity and a range of outputs and services that directly benefit people and nature. The conversion of floodplains from largely natural habitats to a variety of other land uses and the management challenges associated with human use and occupation of floodplains is then described. Changes in land use, demographic patterns, and climate are all contributing to an increase in flood risk. The article summarizes the benefits of managing floodplains for connectivity and then concludes with several case studies that illustrate the multiple benefits for people and nature of restoring or maintaining this connectivity.

Key Floodplain Processes and Benefits

Floodplains are complex systems with physical, biological, economic, and social components (Naiman, Decamps *et al.*, 2005). They are created by flows of water and sediment, which influence, and are influenced by, biological processes. Floodplains are often converted to agricultural and urban development and these land uses are often protected by infrastructure

such as dams and levees. Owing to these complex and interacting components, professionals of numerous disciplines contribute to floodplain science, policy, and management: hydrologists, geomorphologists, ecologists, engineers, planners, sociologists, and policy makers. As a result, there are numerous definitions of floodplains (Nanson and Croke, 1992; Alexander and Marriot, 1999).

From a geomorphic perspective, a floodplain is a depositional feature composed of sediment derived from overbank and in-channel processes of an adjacent water body (Nanson and Croke, 1992; Knighton, 1998). A hydraulic floodplain is a surface that is inundated by a flood of a defined recurrence interval (e.g., the 100-year floodplain that has a 1% probability of being inundated in any given year) whether or not that surface is alluvial (Alexander and Marriot, 1999). This definition is often used by hydrologists and engineers (Nanson and Croke, 1992). For example, the National Flood Insurance Program, administered by the US Federal Emergency Management Agency, requires that communities participating in the Program regulate development in the 1% annual probability hydraulic floodplain (Mount, 1995). Ecologists focus on how hydrological and geomorphic processes shape ecosystem processes (Mahoney and Rood, 1998; Ahearn, Viers *et al.*, 2006) and emphasize the importance of a diversity of flow levels and other hydrologic characteristics (Poff *et al.*, 1997; Opperman *et al.*, 2010).

Hydrological, Geomorphic, and Ecological Processes

Floodplain ecosystems are shaped by the interaction of hydrologic, geomorphic, and ecological processes. Though often viewed as distinct elements – with the river as water and the floodplain as “land” – in reality, a river and its floodplain are one integrated system for conveying water and sediment (Knight and Shiono, 1996).

Tockner and Stanford (2002) characterize river hydrology as “by far the single most important driving variable in floodplains.” Floodplains are highly variable and heterogeneous systems due to the natural variability of river flows (Poff *et al.*, 1997). Riverine hydrology exerts a strong influence on floodplain ecological and biogeochemical processes and, because river flows drive the processes of erosion and deposition that create floodplain topography, also shapes the physical template on which ecosystem processes occur (Poff *et al.*, 1997; Ward *et al.*, 2002). Hydrological processes influence floodplain ecosystems by controlling patterns of connectivity, residence time, and the flows that allow the exchange of organisms, carbon, and nutrients between portions of the landscape (Wiens, 2002).

These linkages between hydrological processes and floodplain geomorphic and ecological processes are driven by a variety of flow levels and other hydrologic parameters. For example, long-duration, high-frequency flood events can be particularly important for food-web productivity and fish reproduction (Junk *et al.*, 1989; Williams *et al.*, 2009), while less frequent, higher magnitude events exert stronger influences on floodplain morphology (Trush *et al.*, 2000). An extensive review of floodplain processes is beyond the scope of this article, but several comprehensive reviews are available (Welcomme, 1979; Junk *et al.*, 1989; Sparks *et al.*, 1990; Nanson and Croke,

1992; Bayley, 1995; Wohl, 2000; Ward *et al.*, 2002; Opperman *et al.*, 2010).

Multiple Benefits of River–Floodplain connectivity

Hydrologically connected floodplains support productive ecosystems and generate a broad range of benefits for people (Gren *et al.*, 1995). These benefits can be characterized as ecosystem services – products and processes generated by functioning ecosystems that economically benefit society (National Research Council (NRC), 2004; Brauman *et al.*, 2007). In their review on the value of the world’s ecosystem services, Costanza *et al.* (1997) found that floodplains were the second ranked ecosystem type, behind only estuaries, in terms of their per-hectare value to society. Despite representing <2% of Earth’s terrestrial land surface area, floodplains provided approximately 25% of all “terrestrial” (i.e., nonmarine) ecosystem service benefits (Costanza *et al.*, 1997). Other researchers have attempted to quantify the benefits provided by floodplains. For example, Sheffer *et al.* (2002) concluded the costs of replacing the goods and services provided by functioning floodplains and found that each hectare of floodplain has a replacement cost of approximately US \$150,000.

Below, several of these benefits are briefly reviewed, with an emphasis on three: agricultural and pastoral productivity, fisheries, and flood attenuation.

Floodplains support high levels of biodiversity (Tockner and Stanford, 2002) for a variety of reasons. Because floodplains often contain a mosaic of habitats – river, wetland, grassland, and forests of varying successional stage – they frequently have high levels of beta diversity (Odum, 1978; Salo *et al.*, 1986), and this habitat mosaic is maintained by fluvial processes that require river–floodplain connectivity. Floodplains also contribute to regional species richness because they often provide unique habitat types not otherwise found in the region (Sabo *et al.*, 2005), such as when a large river flows through a very dry region, or when a region has been largely converted from natural land covers to agriculture or urban development. Within extensively converted landscapes, floodplains can support the last remains of natural habitat and so can continue to support populations of species that would otherwise be extirpated from the region (Odum, 1978). In addition to providing habitat for endangered species, floodplains can support game species (e.g., deer, waterfowl) and provide other recreational and open-space benefits. As discussed below (*see Fisheries*), floodplains connected to rivers can support productive fisheries and thus contribute to commercial and recreational fishing.

During overbank flooding, floodwaters spread out on floodplains and, due to slower water velocities on the floodplain, much of the sediment in transport is deposited there. Because nutrients such as phosphorous are largely adsorbed to sediment particles, this deposition can reduce the loads of sediment and some nutrients in rivers and thus improve water quality for downstream waterbodies, such as estuaries and near-shore marine habitats (Noe and Hupp, 2005). Biogeochemical processes within floodplain wetlands, such as denitrification, can also reduce nitrogen loads in river water (Burt and Pinay, 2005; Valett *et al.*, 2005). Floodplain

reconnection and restoration of floodplain wetlands is therefore recommended as a strategy to reduce nutrient pollution to important waterbodies such as the Chesapeake Bay (Noe and Hupp, 2005) and the Gulf of Mexico (Mitsch *et al.*, 2001). Owing to sediment deposition during recurrent overbank flooding, portions of floodplains can have deep, fertile soil, which can support productive forests (Brinson, 1990; Yarie *et al.*, 1998). Thus, in addition to nutrient sequestration, floodplains can also sequester carbon within rapidly growing trees.

During overbank flooding, a portion of floodwaters can percolate into the shallow groundwater. For example, Valett *et al.* (2005) reported that approximately half of the floodwater entering an experimental semiarid floodplain in New Mexico (USA) contributed to groundwater recharge. The Yolo Bypass, a managed floodplain in California's Sacramento Valley (*see* Floodplain Reconnection for Flood-Risk Reduction), is frequently inundated for long periods of time, contributing to recharge of the groundwater. This recharge supported a valuable "groundwater bank" during a drought (Jericich, 1997). In arid, semiarid, or Mediterranean climate regions, overbank flooding can contribute to ecosystem and agricultural productivity by recharging groundwater and thus increasing the water available during the growing season, particularly if flooding occurs during or relatively soon before a period of drought stress (Robertson *et al.*, 2001). Groundwater recharge is often one of the most important ecosystem services provided by floodplains (Schuyt, 2005), supporting much of the agriculture in parts of Africa (Acharya and Barbier, 2002; Barbier, 2003).

Floodplain Agriculture

This linkage between groundwater recharge and plant productivity is responsible for one of the primary socio-economic benefits of connected floodplains. In Africa, Latin America, and Asia, floodplains that remain hydrologically connected to rivers provide important sites for agriculture and grazing. The flood pulse promotes vital resources for populations in arid and semiarid climates, such as crop production and forage for grazing livestock, by replenishing soil nutrients through sediment deposition and/or recharging groundwater. Depending on various factors (the intensity of water control, the relative importance of rainfall and flood, the type of socio-political institution controlling the natural resources, and the various users' strategies) floodplain agriculture takes different forms along a gradient from rainfed through recession agriculture to irrigation. Below, examples are drawn from Africa to illustrate the mechanisms of floodplain cropping and pastoralism.

Flood-recession agriculture is the most ancient form of floodplain agriculture. Where floods are exogenous (*i.e.*, the majority of the runoff is derived from upstream areas distant from the floodplain), such as in Saharan and Sahelian Africa prior to extensive river regulation, flood-recession agriculture has been the main source of food for vast numbers of people, exemplified by Nile agriculture before completion of the Aswan High Dam. Prior to flow regulation from dams, the Senegal River floodplain supported approximately 200,000 ha of sorghum during the flood-recession, which was the primary food source for more than 500,000 people (Lericollais and Schmitz, 1984). The crop was seeded in November when the

annual flood was receding and harvested from February to April, during the dry season. Flow regulation from dams on the Senegal River negatively impacted floodplain agriculture and grazing, although managed flood releases have subsequently restored some floodplain productivity (*see* Floodplain Reconnection for Restoring Livelihoods) (Hamerlynck and Duvail, 2003). The Tana River floodplain in Kenya supported more than 115,000 Pokomos farmers who depended on recession agriculture prior to dam construction in the 1980s (Emerton, 2003).

In more humid climates, flood-recession agriculture is generally practiced in combination with rainfed agriculture and with various other activities such as fishing, forestry, and livestock-keeping. In these situations, flood-recession agriculture may not be the primary source of food, but it plays an important complementary role to rainfed agriculture. In Tanzania's Lower Rufiji floodplain, more than 100,000 farmers practice flood-recession agriculture within a diversified agricultural system. Farmers plant rainfed maize for the short rains in October–November, which they harvest in December and January. They subsequently plant a second crop of rice that is watered by a combination of an exogenous flood peak (derived from upstream runoff) and local moisture from the long rains occurring between March and May. This crop is harvested in June. During years in which the flood provides sufficient groundwater recharge, the farmers then implement the so-called "Mlao" cultivation of pumpkin, Maize, and cow peas. As a form of flood-recession agriculture that occurs during the dry season, "Mlao" cultivation provides an important "safety net" if either the rainfall failed or the flood was so high it drowned the rice (Duvail and Hamerlynck, 2007).

For vulnerable groups with limited or no access to capital, flood-recession agriculture has many advantages compared to irrigated agriculture. Flood-recession agriculture requires no infrastructure or pumping and no capital outlay except for the seeds. It is also well-adapted to the high hydrological variability of African river systems as crops are only planted in areas likely to succeed – the areas of recent inundation that have fertile and wet sediments. Floods generally remove the dry season vegetation, which greatly reduces the need for soil preparation and weeding. In summary, the workload and capital investment for flood-recession agriculture are low and the productivity is high (Park, 1992; Mollard and Walter, 2008).

People can also convert floodplain resources into food through mobile pastoralism. In Africa, livestock keepers bring their cattle from hundreds of kilometers away to graze post-flood floodplain pastures during the dry season after upland areas have been fully grazed. Floodplain grasses such as *Echinochloa stagnina* ("Bourgou") or *Echinochloa colona* are particularly valued by pastoralists because of their high nutrient content. Approximate estimates suggest that African floodplain pastures can sustain between 40 and 80 head of cattle per km² for up to 8 months, whereas the average surrounding dryland Sahelian pastures can only support 6–8 head per km² for 4 months (Marie, 2009). For example, in the inner Niger delta in Mali, approximately 20,000 km² of flooded surface area, encompassing 1600 km² of *E. stagnina*, supports approximately 1.2 million cattle (60 head per km²; Marie, 2009).

Fisheries

River systems that continue to inundate extensive floodplains support the most productive freshwater fisheries in the world. Floodplains support river fisheries by boosting total productivity and by providing favorable habitat conditions for fish. Productive river–floodplain fisheries are characterized by flood pulses that are predictable and frequent (i.e., a regular annual flood pulse that occurs during the same season) and are of long duration. River systems with these hydrological characteristics are often characterized by a fish fauna with numerous species that have evolved to take advantage of floodplain resources and habitat (King *et al.*, 2003; Winemiller, 2004).

Floodplains support productive fisheries because floodplain habitats often provide beneficial conditions for fish. During floods, the main channels of rivers have high-velocity, turbid water. Floodplains can provide refuge from these harsh conditions with slower-velocity water due to lower gradients and increased hydraulic roughness from trees and other vegetation. During prolonged flooding, floodplain water can become less turbid than river water and warmer, which can benefit fish in cold or temperate regions (Sommer *et al.*, 2001). Flooded terrestrial vegetation and aquatic plants provide abundant cover from predation and, compared to channel habitats where both prey and piscivorous predators can become concentrated, extensive flooding allows fish to disperse over wide areas. These conditions – slow water with extensive cover and reduced concentrations of piscivorous fish – can be ideal for larval and juvenile fish (Welcomme, 1979).

Floodplain habitats also offer abundant food resources for fish, including terrestrial items such as insects, seeds, fruits, and leaves (Chick *et al.*, 2003; Winemiller, 2004), and aquatic food sources. The high primary productivity within the water column of floodplains (Ahearn *et al.*, 2006) supports concentrations of zooplankton and aquatic invertebrates that can be orders of magnitude greater than within the adjacent river (Sommer *et al.*, 2004; Grosholz and Gallo, 2006). The abundant resources on floodplains can provide important nutrition to fish prior to spawning (Moyle *et al.*, 2004) and for larval and juvenile fish after hatching (Ross and Baker, 1983; Sommer *et al.*, 2001; Agostinho *et al.*, 2004; Grosholz and Gallo, 2006).

Illustrating linkages between floodplain inundation and fish productivity, Welcomme (1979) reported that the productivity of fisheries in the Danube River was directly proportional to the extent and duration of inundation of floodplains, and Risotto and Turner (1985) found that the amount of bottomland hardwood forest, which they used as a proxy for floodplain, was a significant predictor of the amount of fish biomass produced by various sections of the Mississippi River and its tributaries. Sommer *et al.* (1997) found that Sacramento splittail year-class strength was correlated with the duration of flooding.

Because floodplains provide high-resource environments, many fish species time their reproduction to coincide with the annual flood pulse and/or spawn within inundated floodplains so that their larvae and juveniles can rear on floodplains (Welcomme, 1979). In tropical rivers, many of the most abundant and economically important fish species spawn only within floodplain habitats, with spawning periods coinciding with predictable, annual flooding (Welcomme, 1979; Hogan *et al.*, 2004).

Rivers that exhibit annual flood pulses onto extensive floodplains have significantly higher productivity of fish per unit area than waterbodies that lack a dynamic flood pulse, including regulated rivers or reservoirs, a phenomenon characterized as the “flood-pulse advantage” (Bayley, 1991, 1995). For African floodplains, Welcomme (1979) estimated an annual production of 50 kg of harvestable fish biomass per ha flooded. The Mekong River supports the largest freshwater fishery in the world and its productivity is derived from the extensive floodplains and lakes inundated by the annual flood pulse. Approximately 60 million people derive their primary source of protein from the fish harvest. Because much of this harvest consists of small fish consumed whole, fish also provide a primary source of calcium and other micronutrients in a region with little access to dairy products (Coates *et al.*, 2003). In the Rufiji River (Tanzania), fish diversity and lake productivity were higher in the well-connected floodplain lakes than in those rarely connecting to the river (Hamerlynck *et al.*, 2011).

In developing countries, small-scale freshwater fish harvests total 14 million tons, with 66% from Asia, 25% from Africa, and 4% from Latin America. These fisheries provide employment to 60 million people and are a primary source of cash income to rural families in Africa and southern Asia. Annual harvest from the Mekong River averages 2 million tons and West African river harvests exceed 1 million tons (UNEP, 2010).

Flood Attenuation

As described above (*see* Key Floodplain Processes and Benefits), floodplains are geomorphic surfaces that are created by flood processes. Rivers in alluvial valleys have the cross-sectional area to convey flows within their banks up to a certain threshold; flows above that level are conveyed by both the river and floodplain. The frequency with which floodplains carry flow varies between rivers, based on characteristics such as river and valley gradient, sediment load, watershed drainage area, and precipitation and runoff regime (Welcomme, 1979; Mitsch and Gosselink, 2000), and ranges from nearly every year to once every few years. In general, floodplains flanking high gradient rivers, and rivers with small drainage areas, have more frequent and “flashier” periods of inundation, whereas floodplains along very low gradient rivers with large drainage areas have fewer peak events with a smoother flood pulse (Mitsch and Gosselink, 2000). For example, portions of the Amazon floodplain are regularly flooded by a single pulse that lasts up to two-third of the year due to the river’s enormous drainage basin with seasonal runoff patterns (Bayley, 1989).

Hydrologically connected floodplains influence flood dynamics and can reduce flood risk to other areas (Figures 1 and 2). Floodplains increase the cross-sectional area to move floodwaters (conveyance) and can also store water and thus reduce the height (stage) of floodwaters (“peak-shaving”). As an illustration of floodplains’ capacity to act like a storage reservoir, the extensive flood basins that historically flanked the Sacramento River (California, USA) temporarily stored and then released approximately 5 bcm (billion cubic meters) annually, effectively delaying peak outflow from the river system by a month (The Bay Institute, 1998).

Figure 1 The Bird's Point-New Madrid Floodway in southeastern Missouri (USA). The floodway is southwest of the confluence of the Ohio and Mississippi rivers at Cairo, Illinois. (a) The Ohio-Mississippi confluence in May 2010 with river discharge within banks; area denoted as "floodway" is dry. (b) The Ohio-Mississippi confluence in early May 2011 during the 2011 flood. Note the floodplain inundation along both rivers and within the southern end of the Bird's Point-New Madrid Floodway. (c) The same location after the floodway levee was breached and floodwaters have entered the floodway. Figure 2 illustrates how using the floodway influenced river stage during the flood. Figure 2 River gages that show the effects of opening the Bird's Point-New Madrid Floodway to increase conveyance in the Mississippi River and to reduce backwater flooding along both Ohio and Mississippi rivers. (a) Real-time gage readings for the USGS gage on the Ohio River at Dam 53 near Grand Chain, IL, approximately 30 km upstream of the floodway. The floodway was opened at 23:00 (11 pm) on 2 May, and the gage shows a rapid response with stage declining approximately one foot in 18 h. (b) River stage on the Ohio River at Cairo, IL, adjacent to the floodway (blue line), Metropolis, Kentucky (red line) approximately 60 km upstream of Cairo, and Old Shawneetown, Illinois (green line), approximately 185 km upstream of Cairo. For display, river stages at all three gages are plotted relative to their height on 7 April 2011. (On their respective gages, Cairo=36.5 ft; Metropolis=34.8 ft; Old Shawneetown=24.8 ft on 7 April). At Cairo, river stage began to decline on 3 May after opening of floodway and declined for the rest of the flood event. The gage at Old Shawneetown shows that the Ohio River flood did not crest upstream until 6 May. Thus, the declining stage at Cairo reflected the increased floodplain conveyance due to the opening of the floodway and not a recession in the flood. The 7 May gage elevation at Cairo was 3.6 ft below the Corps' forecast for Cairo without operation of the floodway. Metropolis and Old Shawneetown gages operated by USGS and Cairo gage operated by the US Army Corps of Engineers. Reprinted with permission from Ted Sommer.

Flood-risk reduction of floodplains can be one of the most important benefits provided by floodplains. For example, a study that assigned economic value to floodplains in Cook County, Illinois (USA) attributed 86% of their value to the regulation of floodwaters (Sheaffer *et al.*, 2002) and Costanza *et al.*, (1997) concluded that “disturbance regulation” represented 37% of the value of floodplains. The presence of extensive hydrologically connected floodplains can reduce flood risks for downstream communities along a river (Klijn *et al.*, 2004) and, conversely, the cumulative loss of upstream floodplain storage, for example, through constriction of the floodplain by levees, can increase flood stages, and thus risk (Criss and Shock, 2001; Pinter *et al.*, 2006).

Along rivers flanked by levees, both peak shaving and increases in conveyance can occur through unintentional levee failures, which allow previously disconnected floodplains to convey and store floodwaters and reduce flood levels downstream. These unintentional flood-risk reduction benefits of floodplains occurred due to levee breaks in the 1927 Mississippi River flood, sparing the city of New Orleans (Barry, 1997), as well during floods on the Missouri and Mississippi Rivers in 1993 (Interagency Floodplain Management Review Committee (IFMRC), 1994) and the Sacramento and San Joaquin rivers in 1997 (McCarthy, 1997). For example, after a levee failed at Sny Island, allowing the flooding of 44,000 acres, the flood stage at Hannibal, Missouri lowered from 31.5 to 27 feet in 2 days (Tobin, 1995). The role of both intentional and unintentional floodplain storage and conveyance are discussed in greater detail below.

Deriving Benefits from Connected Floodplains

The various benefits described above require three primary characteristics: hydrological connectivity, a range of flow levels, including high flows that exceed bankfull, and sufficient spatial scale for the benefits to accrue to a meaningful level (Opperman *et al.*, 2010).

Although exchanges of groundwater between the river and floodplain can influence hydrological conditions for floodplain wetlands and vegetation, surface-water connectivity is required for the performance of geomorphic processes and the exchange of sediment, organic material and organisms between river and floodplain. As river stage rises, surface-water connectivity can occur through lateral overflow, breaks in natural levees (such as sloughs or side channels), unintentional levee breaches, and gates, weirs, or other control structures. Connectivity is maintained during a flood’s recession although the dominant direction of flow is reversed as the floodplain drains back to the river. Following disconnection of surface waters, floodplains can continue to drain back into the river through subsurface pathways and contribute to river baseflow (Ward, 1989).

Floodplain processes are supported by a broad range of flow levels and flow events, ranging from base flows to infrequent, high-magnitude floods (Poff *et al.*, 1997). High-magnitude flood events perform geomorphic work, such as erosion and deposition, and maintain and create floodplain habitat features. Long-duration flooding can be particularly important to many of the benefits described above (Junk *et al.*,

1989; Williams *et al.*, 2009), such as groundwater recharge and fisheries productivity, as fish reproduction and juvenile rearing can require weeks to months of inundation.

A variety of spatial variables influence the production of benefits from floodplains, such as the floodplain’s topographic features and position within the river basin. The extent of connected floodplain is critically important to the production of benefits as floodplain productivity, for fisheries or agriculture, and flood-risk reduction benefits increase directly with area. For floodplain benefits to accrue to a meaningful level, sufficient area of floodplain must be connected.

Changes to Floodplains and Challenges for Water and Floodplain Management

For millennia, people have occupied and used floodplains, drawn by their flat land with fertile soil, proximity to transportation, water supply and water pollution dilution, and the aesthetics of water itself. As a result, floodplains have undergone dramatic conversion globally and are considered one of the most converted and threatened ecosystem types on the planet (Tockner and Stanford, 2002). Particularly in the earlier developing world, most large rivers have become disconnected from a significant portion of their floodplains. For example, less than 10% of historic floodplains remains hydrologically connected to rivers in California’s Central Valley (Bakker, 1972; Barbour *et al.*, 1991; The Bay Institute, 1998) and Mississippi River floodplain forests below the Ohio River have declined by 80% from their historic extent (Llewellyn *et al.*, 1995). In Africa, most of the large rivers have been dammed for irrigation projects causing considerable changes to floodplain extent and processes and the economies that depended on them (Adams, 1996; World Commission on Dams, 2000).

In this section, the authors review the processes that disconnect floodplains from their rivers and facilitate land-use conversions. These changes and conversions have produced many benefits, such as the globally important agricultural economies along major rivers such as the Yangtze and Mississippi. However, these changes have also produced impacts and unintended consequences, such as losses of traditional food-production systems (Adams, 1996; Richter *et al.*, 2010) or increases in flood risk caused by upstream efforts to contain flood flows between levees (Criss and Shock, 2001; Pinter *et al.*, 2006). After describing the processes contributing to floodplain disconnection, the authors review a set of water and floodplain management challenges that can be addressed, in part, by maintenance of restoration of floodplain connectivity.

Just as floodplain benefits require connectivity and flow variability, changes to connectivity and flow are the primary actions leading to floodplain disconnection and land-use conversion. Levees and floodwalls are built to contain floodwaters and physically disconnect floodplains from river surface water. Levees have been constructed along major rivers for centuries and were first built on the Yangtze and Yellow Rivers more than 4000 years ago, and on the Rhine, Mississippi, and Sacramento Rivers in the eighteenth and nineteenth centuries (Sayers *et al.*, 2011). Levees are generally built to protect existing development investments on floodplains, such as agriculture and residential and commercial buildings, and/or to facilitate future

Figure 3 Discharge of two adjacent rivers in California's Central Valley. The Cosumnes is essentially unregulated and displays natural flood peaks (solid line). The Mokelumne (blue line with hatching) is regulated by two large dams that provide flood control, in addition to hydropower and water-supply storage. Reprinted with permission from Jeff Mount.

investment. The USA currently has approximately 23,000 km of levees managed by the US Army Corps of Engineers and potentially more than 160,000 km of nonfederal levees (National Levee Safety Committee, 2009). Dams regulate river flows, with flood-control dams operated specifically to store floodwaters and reduce downstream flood peaks (Figure 3). Dams operated for water supply, irrigation, and hydropower also often reduce downstream flood peaks because they capture water during periods of high flow to store and release later during periods of low flow (Ligon *et al.*, 1995).

Land and Water Management Challenges

Current water and floodplain management, including the extensive conversion of floodplains from largely natural to developed landscapes, has produced numerous benefits for society. However, this land and water management has also created a legacy of impacts, and current approaches may not be adequate for future challenges. The sections below describe several of these challenges, both legacy and future, which can be addressed in part through floodplain reconnection or conservation.

Declines in Freshwater Biological Diversity and Productivity

The extensive conversion of floodplains and alteration of rivers has contributed to dramatic declines in biodiversity and populations of commercially, recreationally, or culturally important species. Freshwater species are imperiled at far higher rates than terrestrial or marine species (Ricciardi and Rasmussen, 1999) and a primary cause is fragmentation, flow alteration, and river–floodplain disconnection caused by dams and levees (Poff *et al.*, 1997; Richter *et al.*, 1997; Tockner and

Stanford, 2002). Freshwater fisheries have declined dramatically from rivers following widespread floodplain disconnection and flow alteration. For example, the Missouri River commercial fish harvest declined 80% from the 1880s to the 1990s due to flow regulation and levee construction (Galat *et al.*, 1998).

Impacts to River-Dependent Communities and Livelihoods

These declines in floodplain extent and function have had negative impacts on millions of river-dependent people worldwide (Richter *et al.*, 2010). Along the lower Tana River in Kenya numerous indigenous communities derived socio-economic values from the annual inundations of the floodplain and delta, including fisheries, flood-recession agriculture, and pastoralism (Terer *et al.*, 2004). The construction of the series of hydropower dams in the upper basin altered flow regimes including decreasing peak flows during the wet season (Maini and Marsh, 2002). The resulting reduction of flooded surface area, flood peak duration, and meandering dynamics have negatively affected floodplain productivity and forest regeneration and therefore the local economies (Hamerlynck *et al.*, 2010).

In the 1980s, the Senegal River Basin Development Authority, representing Mali, Guinea, Senegal, and Mauritania developed a project on the Senegal River to produce hydropower, improve navigation, and develop irrigated agriculture on 375,000 ha of the valley's floodplains. The project consisted of two large dams: a multipurpose dam at Manantali in Mali (hydropower and irrigation) and a "salt wedge" dam at Diama close to the river mouth, to prevent saltwater intrusion. Expectations for the productivity of irrigated agriculture have not been met, in spite of huge investments (1500–6500 US\$ per ha) (Hamerlynck *et al.*, 2005). The

negative impacts of the dams on fisheries (Bousso, 1997), the environment, and human health (Verhoef, 1996) have been considerable and the livelihoods of the valley's inhabitants have been seriously affected (Adams, 1999). For example, flood-recession sorghum farming diminished drastically in the 1970s and 1980s due to both drought and flow regulation from upstream dams, but rebounded somewhat after the failure of the irrigation schemes and the implementation of the managed flood releases from Manantali (*see Floodplain Reconnection for Restoring Livelihoods*) (LeRoy, 2008).

Rising Flood Risk and Aging Infrastructure

Although flood-management infrastructure in the USA has allowed greater economic utilization of floodplains, it has also compromised many of the natural benefits provided by river–floodplain systems and encouraged development in places vulnerable to periodic damaging floods (Association of State Floodplain Managers, 2008). Flood damages in the USA have increased over the past century, from less than US\$1B annually in the 1930s to more than US\$6B currently (in constant dollars) (Pielke *et al.*, 2002), even as billions have been spent to build and maintain dams and levees to manage floodwaters.

Several trends suggest that flood risk will continue to increase in the USA and in other developed countries. First, development continues in places vulnerable to flooding whereas upstream land-use changes, such as an increase in impervious surfaces, continue to alter runoff and downstream flood dynamics (Pinter, 2005). Many of the nation's dams require extensive rehabilitation, with an estimated 5-year price tag of US\$12.5B including 1743 high hazard dams in need of repair. Levee maintenance is chronically underfunded (Leavenworth, 2004b), requiring an estimated 5-year investment of US\$50B (American Society of Civil Engineers, 2009). Further, forecasts indicate that climate change may lead to greater flood magnitudes and frequencies. Evaporation rates increase with air temperature, and warmer air can hold more water vapor, increasing the intensity of heavy precipitation events (Kundzewicz *et al.*, 2008). Owing to these trends, flood risks are greater than commonly perceived and are growing.

Competition between Water-Management Sectors

Reservoirs that provide flood control often also provide multiple purposes, such as water supply, hydropower, and recreation, and these various objectives can compete with each other. Flood control is maximized by maintaining low reservoir levels during periods of flood risk whereas hydropower generation is maximized by high reservoir levels. Water supply risk can increase when reservoirs are lowered for flood control; for example, if the basin enters a period of drought after reservoir drawdown. These conflicts may be exacerbated by climate change, which is forecasted to increase the “flashiness” of precipitation and runoff and thus may increase both flood and drought risk in many parts of the world (Kundzewicz *et al.*, 2008).

Floodplain Reconnection and Conservation

This section reviews the methods to maintain or restore floodplain connectivity, encompassing both physical connectivity and the flow regime. Several examples of floodplain

reconnection for a variety of primary objectives are then described.

Methods to Maintain or Restore Floodplain Connectivity

Hydrologically connected floodplains provide a range of benefits. Achieving these benefits requires either maintaining existing floodplain connectivity or reconnecting floodplains. Connected floodplains can be maintained through real-estate transactions such as acquisition, easements, or government funding programs, such as the Wetland Reserve Program. For example, to maintain the capacity for floodplains to be inundated along the Savannah River (Georgia/South Carolina, USA), The Nature Conservancy (TNC) is working with willing landowners to acquire or place under easements floodplain land to maintain it in low-intensity land uses (Opperman *et al.*, 2010). In the 1970s, the US Army Corps of Engineers studied alternatives for reducing flood risk for Boston from the Charles River and concluded that acquisition and protection of floodplain wetlands could provide similar protection as new levees and flood-control reservoirs for approximately one-tenth the cost. The Corps acquired 3440 ha in the Charles River floodplain for approximately US\$10 million (Postel, 2005). In addition to acquisition or easements, emerging markets for ecosystem services, including carbon and nutrient sequestration, floodwater storage, and recreation may be able to provide revenue to landowners that maintain floodplains connected to rivers (Opperman *et al.*, 2009, 2010).

Reconnecting floodplains can be accomplished through physical reconnection (removing barriers between river and floodplains), hydrological reconnection (such as the release of environmental flows), or a combination of the two. Managing dam operations to release high flows to mimic floods is a specific example of environmental flows (Postel and Richter, 2003).

Floodplain connectivity on the Cosumnes River (California, USA), an unregulated river draining the Sierra Nevada (Figure 3), was restored by cutting breaches through an existing levee. Levee breaches were also used on Mollicy Farms to reconnect 6400 ha of floodplain to the Ouachita River (Louisiana, USA) (Opperman *et al.*, 2010). In many locations in the USA, levees have been set back further from the river to reconnect portions of the floodplains, such as on the Sacramento, Bear and Feather rivers in California (Williams *et al.*, 2009; Opperman *et al.*, 2010). Along both the Sacramento and Mississippi Rivers, flood-management strategies evolved from a “levees only” approach, which disconnected nearly the entire floodplain from the river, to the reconnection of large areas of floodplain (tens of thousands to hundreds of thousands of hectares) as flood bypasses or floodways (US Army Corps of Engineers, 2004). The Yangtze River (China) has similar features known as Flood Detention Areas, while the Meuse, Rhine, and Elbe rivers in northern Europe have a system of polders that can be intentionally flooded to reduce flood stages in the river (Klijn *et al.*, 2004; Forster *et al.*, 2005). For these features, river–floodplain connectivity is regulated by weirs, fuseplug levees, or gates. The frequency of connection of these managed floodplains ranges from nearly every year (Yolo Bypass on the Sacramento River; Sommer *et al.* (2001)) to once or twice a

century (New Madrid Floodway on the Mississippi and the Jingjiang Flood Detention Area on the Yangtze) (US Army Corps of Engineers, 2004).

The operation of dams can be modified to restore characteristics of the flood pulse to increase river–floodplain connectivity and promote floodplain benefits. Flood releases from reservoirs can be designed to replicate various characteristics of historical flood patterns, such as magnitude, season, duration, or rate of change (Postel and Richter, 2003). For example, an experimental flood released from Alamo Dam on the Bill Williams River (Arizona, USA) favored the regeneration and growth of native riparian willows (*Salix spp.*) over invasive Tamarisk (Shafroth *et al.*, 2009). On the Truckee River (Nevada, USA), dam operators mimicked the gradual recession of the snowmelt hydrograph and promoted regeneration of the willow–cottonwood floodplain forest (Rood *et al.*, 2003). Several dams in Africa have released experimental floods intended to restore downstream floodplain ecosystems and livelihoods (Hamerlynck and Duvail, 2003; Loth, 2004).

Managed flood releases cannot address all impacts from dams, but can restore some ecosystem functions and thus continue to ensure the livelihoods of the downstream populations (Acreman, 2003). A variety of methods can be used for developing environmental flow recommendations, including managed floods, (Tharme, 2003) and integrating these environmental flows into dam operations (Harman and Stewardson, 2005; Beilfuss, 2010; Esselman and Opperman, 2010).

For rivers with natural or close-to-natural flow regimes, restoration of physical connectivity will allow restoration of floodplain processes and many associated benefits. For rivers below dams, restoring physical connectivity will likely not restore all floodplain processes, depending on the degree and type of flow alteration. For example, a levee setback project on the Sacramento River at Hamilton City will increase the connectivity between river and floodplain for a range of flow types. However, without alternative flow management from the upstream Shasta Dam, the reconnected floodplain will only rarely experience ecologically important long-duration spring flooding, which was frequently common (Williams *et al.*, 2009; Opperman *et al.*, 2010). Similarly, projects focused on restoring flood releases from dams may also need to consider the downstream physical connectivity. For example, restoration of floodplain processes on the Logone River (Cameroon) required both managed flood releases and removal of barriers to river–floodplain connectivity (Loth, 2004).

Floodplain Reconnection for Restoring Ecosystems and Services

The Cosumnes River is one of the only remaining major rivers draining the western slope of the Sierra Nevada that does not have any large dams on the mainstem and, therefore, high flows on the Cosumnes are mostly unchanged from their natural condition (Moyle *et al.*, 2007) (Figure 3). TNC, along with numerous partners, established the Cosumnes River Preserve (CRP) along the lower river. In 1985, an agricultural levee adjacent to the CRP breached, allowing flooding and sediment deposition. Riparian trees, including cottonwoods and willows grew rapidly in the freshly deposited sediment.

This area, now referred to as the “accidental forest,” became part of the preserve in 1987 and currently has a tall canopy of cottonwoods with an understory of valley oaks (Tu, 2000; Swenson *et al.*, 2003). Owing to the successful riparian regeneration following the 1985 breach, TNC sought to increase connectivity between the river and floodplain through additional breaches in the remnant agricultural levee. After hydrological modeling indicated that a new breach would not increase flooding for neighboring landowners, TNC opened up two new breaches in the levee in 1995 and 1997. (Swenson *et al.*, 2003). Prior to the breaches, the levee contained floods up to about the Q_5 (0.20 exceedance probability in any year). After the breaches, hydraulic connectivity initiates at flows only half the size of the mean annual flood, with an annual exceedance probability of 0.95 (Mount *et al.*, 2003).

Florsheim and Mount (2002) demonstrated the significance of rare, large flow events in creating dynamic floodplain topography on the Cosumnes. Sand splay complexes formed at levee breaches increase topographic heterogeneity on the floodplain and promote recruitment of riparian trees (Tu, 2000; Florsheim and Mount, 2002). The Cosumnes floodplain is frequently flooded for long durations (weeks to months) in the spring, which is particularly important for promoting food-web productivity on floodplains. This type of flooding was once common in California’s Central Valley but now, due to flow regulation and levees, is relatively rare (Williams *et al.*, 2009). During this long-duration flooding, the floodplain is the site of high algal productivity (Ahearn *et al.*, 2006), which leads to concentrations of zooplankton and invertebrates that are 10–100 times greater on the floodplain than in the river (Grosholz and Gallo, 2006). This productivity benefits native fish (Moyle *et al.*, 2007) and Jeffres *et al.* (2008) demonstrated that juvenile salmon rearing on the floodplain grow significantly faster than juvenile salmon rearing in adjacent river habitats.

At Mollicy Farms along the Ouachita River (Louisiana, USA), a tributary to the Mississippi River, TNC also opened levee breaches to restore connectivity to 6400 ha of marginal agricultural land on the floodplain. The restoration is projected to have local benefits for wildlife but a key feature of the restoration project is research and monitoring to determine the potential for large-scale reconnection to promote system-scale benefits. Researchers at Mollicy Farms are quantifying the ecosystem services of recreation, carbon sequestration, and nutrient sequestration. This research is intended to further understand the potential for markets for these ecosystem services and for these markets to provide revenue to landowners that would be comparable to crops (Opperman *et al.*, 2010). Nutrient sequestration could potentially be compensated through a market-based approach to reduce nutrient loading to the Gulf of Mexico, which results in a massive “dead zone” each year (Mitsch *et al.*, 2001).

Floodplain Reconnection for Restoring Livelihoods

Cameroon’s Logone River was dammed in 1979, forming Lake Maga, and subsequent flow regulation diminished the extent of annual flooding downstream, negatively impacting floodplain-dependent communities. In the 1990s,

dam managers released experimental floods intended to re-inundate the floodplain and restore economic activities such as grazing and fishing (Loth, 2004). In the experimentally flooded area, cattle numbers increased 260% in part due to an increase in cover of nutritious perennial grasses such as *Echinochloa pyramidalis* and *Oryza longistaminata*. Fish harvest within the flooded area was 90 kg ha⁻¹ (Loth, 2004).

On the Senegal River, flow regulation from dams greatly reduced flooding and, by the early 1990s, most of the Mauritanian lower delta of the Senegal River had turned into a saline desert. In the dry season, hypersaline conditions downstream of Diama Dam were degrading natural vegetation communities (*Avicennia germinans* mangrove, *Sporobolus robustus* grasses, and *E. colona* pastures). Between 1994 and 1996, water managers constructed embankments and sluice-gates to manage flows to simulate the predam hydrodynamics on the former floodplain. Through a participatory approach, the water requirements of various local user groups (fishers, livestock keepers, and gatherers) and of the National Park authority were analyzed, modeled, and reconciled with the imperatives of the basin's water-management authority. A number of flood scenarios to increase floodplain productivity were proposed, discussed, tested, and formalized in a management plan approved by all stakeholders and government institutions in 1997. The effect of the managed flood releases on various components of the ecosystem was quantified and the flood scenario improved through an iterative consultative process (Hamerlynck and Duvail, 2003).

The Sahelian ecosystems proved resilient and most of the floodplain functions were restored after a few years of managed flooding, although restoration of the floodplain-associated Acacia and mangrove forest took longer (at least 10 years) (Hamerlynck and Duvail, 2003). The restoration of floodplain productivity allowed local inhabitants to resume their traditional livelihood activities. An economic evaluation has shown that the restored area produces about 65 US\$ of added value per ha per year through the extractive activities of the local communities (Moulaye Zeine, 2004). By stemming the rural-to-urban migration of young men this economic revival has also contributed to an improved social equilibrium. Interestingly, the stakeholders recommended, and managers were able to implement, a period of inundation during the May dry season when the floodplain would have been dry under the natural hydrological pattern. This counter-season inundation has increased the productivity of the floodplain compared to the natural flooding pattern and provides access to water for cattle during the dry season and can serve as emergency pasture (Duvail and Hamerlynck, 2003).

Floodplain Reconnection for Flood-Risk Reduction

Traditional approaches to managing floods have emphasized structural solutions, such as levees and dams. Increasing flood damages in spite of massive investments in structural approaches highlighted the need for nonstructural measures, such as land-use planning, building codes, insurance, and use of the natural and beneficial functions of floodplains, including storage and conveyance. Accompanying the increased emphasis on nonstructural measures, many water managers

and floodplains managers now refer to “flood-damage reduction” or “flood-risk management” rather than “flood control” (Klijn *et al.*, 2004). The concept of flood-risk management acknowledges that no set of actions can guarantee the prevention of flooding; structural measures can fail or have their design level of protection exceeded and thus some level of residual risk will be inevitable. As a result, flood-risk management proposes that flooding challenges should be addressed through a portfolio of measures, including both structural and nonstructural, emphasizing those actions which provide for sustainability and long-term use of the flood attenuation characteristics of natural systems. The use of floodways and off-river storage areas are receiving significant attention as new plans are prepared to deal with the growing challenges of climate change and increasing population in flood-prone areas (Klijn *et al.*, 2004; Freitag *et al.*, 2009; Opperman *et al.*, 2009; Sayers *et al.*, 2011).

Although gaining renewed attention, the strategy of using floodplains to store and convey floodwaters is not new; the reconnection of floodplains to reduce flood risks is a feature of flood management on major rivers such as the Yangtze, Mississippi, and Sacramento. For both the Mississippi and the Sacramento, the floodplain reconnection occurred in the aftermath of major flood disasters that revealed the weakness of the existing paradigm for flood management, a “levees only” approach that attempted to confine the river between levees and essentially disconnect the entire floodplain (Kelley, 1989; Barry, 1997).

In 1927, a historic flood on the lower Mississippi overtopped, or caused the failure, of dozens of levees, inundating 70,000 km² and displacing 600,000 people (US Army Corps of Engineers, 2004). Hundreds, and more likely thousands, of people died (Barry, 1997). River and floodplain management prior to the flood had relied on levees to contain floodwaters and was composed of multiple, disjointed efforts. Following that flood, the US Army Corps of Engineers developed a comprehensive plan for navigation and flood protection in the lower Mississippi Valley. The plan proposed and later implemented by the Corps included use of storage behind dams, setback of levees to provide more room for conveyance of floodwaters, and the use of floodways and backwater storage areas to relieve pressure on levees protecting major urban areas (and thereby reduce the necessity to raise levees to meet growing increases in flood flows).

The system that was developed included four portions of the historic floodplain that were designated as floodways – the Birds Point-New Madrid (in southeast Missouri; Figure 1) and the West Atchafalaya, Morganza, and Bonnet Carré (all in Louisiana). During the highest flow events, floodwaters can leave the river and enter the floodways through fuseplug levees or gates. The floodways can carry a significant portion of water during floods, lowering flood stages elsewhere and reducing pressure on levees (Figure 2). For example, for the “project design flood” (the maximum flood with a reasonable probability of occurring), the New Madrid floodway is designed to convey nearly one-fourth of the flow below the confluence of the Ohio and Mississippi rivers and, near the Gulf of Mexico, the main channel of the Mississippi is designed to carry approximately 40% of total flow with the remainder moving through floodways, primarily the Old River Diversion and the

Morganza Floodway in the Atchafalaya Basin (US Army Corps of Engineers, 2008).

The effectiveness of floodplains for contributing to flood-risk management was demonstrated during major floods in the lower Mississippi Valley in 1973 and 2011 when use of floodways in Missouri and Louisiana relieved pressure on levees protecting Cairo, Illinois, and the major urban industrial areas from Baton Rouge to the Gulf of Mexico along the Mississippi. Diversion of Mississippi waters into the floodways increased conveyance in key locations and allowing water to accumulate in the backwater areas (where major tributaries enter the Mississippi) reduced peak stages. Although the flood of 2011 had a greater volume than the 1927 flood, no levee failures or deaths occurred in 2011.

The Sacramento River (California, USA) followed a similar trajectory as the Mississippi: disjointed river and floodplain management that relied almost strictly on levees, disastrous floods and levee failures exposing the flaws of a “levees only” approach, followed by a systematic approach to floodplain and river management that featured large-scale reconnection of floodplains. Flood management in the Sacramento Valley relies to a great extent on a system of bypasses, portions of the historic floodplain connected to the river by weirs. When river stage exceeds the weir elevation, floodwaters enter the bypasses. The Yolo Bypass, a portion of the low-lying Yolo Basin that flanked the Sacramento River, was reconnected to the Sacramento River in the 1930s (Figure 4). During major floods, the Bypass carries 80% of the volume of floodwaters while the river channel, adjacent to the city of Sacramento, carries only 20% (Sommer *et al.*, 2001). As described further below, the Yolo Bypass is a central feature for flood-management in the Sacramento Valley. Beyond flood management, the Bypass provides a variety of other benefits. Approximately two-thirds of the Bypass is in active agriculture with annual crops. The Bypass also provides open space, recreation (primarily duck hunting and wildlife viewing), and groundwater recharge that proved valuable as a groundwater bank during a drought (Jercich, 1997; Sommer *et al.*, 2001). The Bypass is also considered one of the most important remaining floodplain habitats in the Central Valley for ecologically important Spring flooding (Williams *et al.*, 2009) and for providing habitat for native birds and fish (Sommer *et al.*, 2001). Owing to high floodplain productivity, juvenile Chinook rearing in the Bypass grow faster than juveniles rearing in the adjacent Sacramento River (Sommer *et al.*, 2001) and the Bypass has population-level benefits for the obligate floodplain spawner, the Sacramento splittail (Sommer *et al.*, 1997).

California provides several other examples of projects that reconnected floodplains with a primary objective of contributing to flood-risk reduction. The city of Napa selected a flood management plan based on levee setbacks, bypass channels, and floodplain reconnection to lower flood risk, rejecting a typical approach of dredging and tall floodwalls that would have been considerably more expensive and would have visually and physically disconnected the river from the town (Postel, 2005). On the Bear and Feather rivers (tributary to the Sacramento), the Three Rivers Levee Improvement Authority selected levee setbacks as the most effective way to overcome erosion risk to certain levee segments and to increase conveyance to reduce backwater flooding (Leavenworth, 2004a).

Though driven by flood management objectives, the projects will restore thousands of hectares of riparian forest.

Removal of buildings and relocation of residents from floodplains can be a component of flood-risk management (US Army Corps of Engineers, 2001). Generally, this approach is implemented to avoid repetitive losses in areas with high flood risk. In the USA, due to the sensitivity of federal land acquisition, federally supported relocations are voluntary. For example, the town of Valmeyer, Illinois, which was inundated by the 1993 Mississippi River flood, was relocated from the floodplain of the Mississippi to bluffs approximately 2 miles away using funds from the Hazard Mitigation and Grant Program of the Federal Emergency Management Agency and other sources (Bello and Eisler, 2008). Because of the very high cost of developed land, most proposals for, or analyses of, large-scale floodplain reconnection focus on agricultural or other land that is either uninhabited or sparsely settled (Klijn *et al.*, 2004; Sparks and Braden, 2007).

Floodplain Connectivity to Increase the Operational Flexibility of Multipurpose Reservoirs

As described above, within multipurpose reservoirs, the various water-management purposes can compete with each other for reservoir allocation. Forecasts for increased risk of both drought and flood with climate change (Kundzewicz *et al.*, 2008) may exacerbate the conflict between flood control, which benefits from lowering reservoir levels in preparation for the potential need to store and regulate flood inflows, and purposes that benefit from full reservoirs (hydropower, water supply, release of environmental flows, and recreation).

Large-scale floodplain reconnection, or maintenance of connectivity, can potentially shift some of the flood-management burden onto downstream floodplains and thus reduce flood-management obligations within the reservoir. Coupling floodplain and reservoir management can potentially increase the flexibility and resiliency of multipurpose reservoirs. With reduced flood-management responsibility, a multipurpose reservoir could generate more hydropower or have greater water-supply security heading into droughts. For example, Opperman *et al.* (2011) summarize an analysis of alternative operations for a cascade of dams on the upper Yangtze River, which suggests that reducing flood storage from the reservoirs and shifting flood-risk management to the downstream floodplain can provide equivalent or lower flood risk, greater environmental performance, and hundreds of millions of dollars more in annual hydropower revenue because the reservoirs can be maintained at higher levels.

The Yolo Bypass, described above, provides another illustration of this concept (Figure 4). Although the Bypass was built decades before a system of multipurpose reservoirs in the Sacramento Valley, it effectively illustrates how a geographically large hydrologically connected floodplain can increase the flexibility of multipurpose reservoirs (Opperman *et al.*, 2011). By conveying 80% of the volume of floodwaters during major floods, the Bypass floodplain relieves pressure on levees and substitutes for billions of cubic meters of reservoir flood storage. Opperman *et al.* (2011) present an analysis of the role

Figure 4 Location of the Yolo Bypass (shaded gray), and its major features, within the lower Sacramento Valley, California.

the Bypass played in the Sacramento Valley flood management during a flood in 1986 (a 50–80-year recurrence interval flood at the city of Sacramento). During the 3-day peak of the 1986 flood (19–21 February) 3.3 bcm flowed through the bypass, which is approximately the same volume as the combined flood-control storage of the six major reservoirs that manage floodwaters in the Sacramento River basin (Figure 5). During this peak, the multipurpose reservoirs' flood storage volume was nearly full and the Sacramento River was essentially at its channel capacity (i.e., greater discharge within the channel would have led to levee overtopping). Thus, the 3.3 bcm that flowed through the Bypass during the peak 3 days could not have been stored or conveyed by any other element of the existing flood-control system. The "green infrastructure" of the Bypass floodplain was providing a service that could not have been provided by the existing engineered infrastructure.

Managing the volume of water associated with the 1986 flood without the Bypass floodplain, let alone a 100- or 200-year event, would require some combination of (1) additional flood-control infrastructure, including new dams and extensive rising of levee height to increase channel capacity; and (2) considerable reallocation of existing reservoir storage from water supply to flood control. The first would require significant funding – in a state where maintenance of the current levee system is chronically underfunded (Leavenworth, 2004b) – while the second would impinge on California's already strained water supply resources. Thus, the hydrologically connected floodplain of the Yolo Bypass is essential for the operational integrity and flexibility of the current system of water storage and allocation and provides a considerable economic value in the form of avoided costs for additional infrastructure.

Figure 5 Volume of water conveyed by the Yolo Bypass during the 1986 flood event and volume of water in Sacramento River reservoirs.

Conclusions

Hydrologically connected floodplains provide multiple benefits to people and nature. From the perspective of environmental resources, floodplains are among the most diverse and productive ecosystems on the planet. Much of their value to people flows directly from that biological productivity and diversity and from processes that require floodplain inundation. These include fisheries, groundwater recharge, nutrient sequestration, and flood-dependent forage vegetation and flood-recession agriculture. Most of these floodplain benefits are associated with frequent and long-duration flooding, such as an annual, extended flood pulse.

However, floodplains are also globally important as sites of high agricultural productivity with crops that are not tolerant of flooding (e.g., corn, wheat, and soybeans). By storing and conveying floodwaters, hydrologically connected floodplains also can promote the production of these benefits by reducing flood risk for flood-intolerant agriculture. Flood-risk reduction services of hydrologically connected floodplains can occur across a gradient of floodplain management, encompassing extensive “natural” floodplains, strategically located levee setback projects, frequently inundated flood bypasses that encompass a mix of natural and agricultural land use (e.g., the Yolo Bypass), and floodways that are only used during relatively rare, high magnitude floods (e.g., the floodways on the Mississippi River). Through this gradient of floodplain management, floodplains that serve to reduce flood risk can continue to support productive agriculture and provide revenue to landowners, as exemplified by the Yolo Bypass (Sommer *et al.*, 2001). Flood-tolerant crops and current or potential markets for ecosystem services such as groundwater recharge, recreation, and nutrient and carbon sequestration can also support private landowners and agricultural economies (Opperman *et al.*, 2009; Opperman *et al.*, 2010).

Although the previous three sections described floodplain restoration for specific purposes, such as promoting flood-dependent livelihoods, a hallmark of floodplain connectivity is

that it tends to produce multiple benefits. For example, while the case study for the Senegal Delta focused on livelihood benefits, the project also produced important benefits for biodiversity. The Yolo Bypass was conceived strictly as a flood-control project, but decades later scientists recorded its immense value for the native species of California’s Central Valley, providing some of the most important remaining floodplain habitat in the lower Valley. Even the rarely used floodways of the Mississippi River had high food-web productivity from weeks to months of inundation in 2011, and will likely contribute a strong year class of fish, based on the fish response to the 1993 flood on the Mississippi (Jones and Noltie, 2007).

The feasibility of implementing floodplain reconnection projects, or maintaining existing connectivity, can be improved if these multiple benefits can be identified and captured. The levee setback project at Hamilton City was only financially feasible because it could identify benefits to both flood-risk reduction and ecosystem restoration, and it drew on funding sources for both services. The floodplain reconnection project at Mollicy Farms includes a study of the values provided by ecosystem services such as recreation and carbon and nutrient sequestration to determine if the “stacking” of these multiple services can provide comparable revenue to agriculture for landowners of flood-prone cropland (Opperman *et al.*, 2010).

The challenge of accounting for the full diversity of benefits provided by hydrologically connected floodplains has contributed to floodplains being undervalued within studies for development projects. In the developing world, people use floodplains for a wide variety of purposes depending on the season or type of year (e.g., wet or dry), including fishing, flood-recession agriculture, irrigated agriculture, pasture, timber and nontimber forest products, and wildlife. Often most or all of these uses exist outside of market economies and thus can be quite difficult to measure and enter into cost-benefit analyses to compare alternatives for water management within a development project. Focusing on a single purpose of floodplains, such as comparing flood-recession agriculture to irrigated agriculture, will not account for the full value that floodplains may provide to rural people. Failure to fully account for these values is undoubtedly one of the primary reasons that many water development projects have not produced net positive benefits for rural people (Richter *et al.*, 2010). Going forward, funders and planners of development projects should ensure that the full range of values of hydrologically connected floodplains is accurately measured to facilitate sound analyses and decisions.

These multiple values should also be considered by agencies and organizations tasked with helping society manage changing risks, including risks associated with climate change. Although the hydrological implications of climate change for total precipitation are less certain than forecasts of temperature rise, most forecasts suggest an increase in the frequency of extreme hydrological events, such as floods and droughts (Kundzewicz *et al.*, 2008). Floodplain reconnection or conservation can be considered a form of “ecosystem-based adaption” to climate change and can potentially address both types of extreme events. By storing and conveying floodwaters, floodplains can contribute to flood-risk reduction objectives. By contributing to groundwater recharge and reducing the need for flood-control storage volume within multipurpose

reservoirs, hydrologically connected floodplains can also contribute to increased water security to manage drought risk. Corresponding to ecosystem-based adaption projects generally, floodplain reconnection or conservation offers a broad range of benefits beyond managing risks associated with potential hydrological perturbations from climate change. Because of these multiple benefits, floodplain projects can be considered “no regrets” projects, meaning they still produce values even if the predicted climate-change perturbations do not materialize.

Glossary

Institutions Humanly devised constraints that shape human interaction and the way societies evolve through time; made up of formal constraints (rules, laws, constitutions), informal constraints (norms of behavior, conventions, self-imposed codes of conduct), and their enforcement characteristics.

Natural disturbance Any relatively discrete event in time that disrupts ecosystem community or population structure and changes resources, substrate availability, or the physical environment; key for structuring biological communities and for maintaining resilience in ecological systems.

Resilience The system's capacity to absorb disturbance and conserve opportunity for self-organization and evolution. Resilience has to do with how resistant the

system is to fundamental reorganization such as a phase shift into another stability domain.

Social taboo A prohibition imposed by social custom or as a protective measure.

Traditional ecological knowledge A cumulative body of knowledge, practice, and belief, evolving by adaptive processes and handed down through generations by cultural transmission, about the relationship of living beings (including humans) with one another and with their environment.

Traditional peoples Various referred to as indigenous peoples, native peoples, or tribal peoples; peoples with cultures that differ from those of the mainstream of a national population, having distinct ethnic languages with locally evolved resource management systems; currently some 5000 distinct indigenous peoples exist in the world.

Introduction

Even traditional peoples with a relatively high human population number were able to utilize rain forest areas without destroying these environments and surrounding biological communities (Primack, 1993). However, the specific objective of these local practices is not necessarily directed toward the conservation of species, their habitats, and ecosystems. Rather, such practices are often geared for sustainable use of local resources and ecosystems, with biological conservation resulting as an indirect outcome. They are often tied to cultural belief systems, which makes it difficult to separate the belief component from actual management practices and the ecological knowledge system on which they build. Knowledge, practices, and beliefs tend to intermingle in most traditional management systems (Gadgil *et al.*, 1993). This constitutes the basis behind traditional ecological knowledge (TEK), denoting that resource management patterns are the products not only of a people's physical environment and its resources but also of their cultural perceptions of the environment and its resources (Ruddle, 1994).

Cultural belief systems of various peoples have protected species, their habitats, and even smaller ecosystems. For example, several verses in the Vedas and Upanishads mention conservation and protection of plants and animals, indicating that traditional conservation practices of many rural and indigenous groups of India go as far back as the Vedic period (5000 B.C.). In fact, a great deal of social mechanisms, such as social taboos, may be highly adaptive from an ecological perspective and contribute to biodiversity conservation (Colding and Folke, 1997). The term *conservation* is here used

in the sense of sustainable use of natural resources for human benefit, without compromising the interests of future generations (WCED, 1987).

This article will provide examples of a diverse set of traditional management practices and institutions that exist among local resource users. We will illustrate that such practices play an important role for *in situ* conservation of biological resources. We deal with traditional management practices that lead to the sustainable use of biological resources and local institutions and belief systems that impose regulations on the use of species and access to ecosystems.

The word *traditional* refers here to the historical and cultural continuity of resource management, recognizing that societies are constantly redefining what is considered "traditional." The term "local resource users" refers to both traditional peoples and small-scale societies of Western countries with locally evolved management systems. Local resource users generally depend on a rather limited resource procurement base to provide them with a wide diversity of resources (Gadgil *et al.*, 1993). Many do not have access to fossil fuel dependent technology or capital markets. Their day-to-day survival depends on proper interpretations and knowledge of the dynamics of their local resources and ecosystems. Thus, they often have a stake in managing their resources for long-term endurance.

Many of the examples of management practices and local institutions presented in this article derive from the case study anthology edited by Berkes and Folke (1998). This anthology predominantly deals with local resource users that display success of long-term environmental management by using practices that contribute to building resilience in local

Figure 1 Focus of analysis of linked social-ecological systems. Ecological knowledge and understanding is a critical link between complex and dynamic ecosystems, adaptive management practices, and institutions.

In: Berkes F and Folke C (eds.) *Linking Social and Ecological Systems. Management Practices and Social Mechanisms for Building Resilience*. Cambridge, UK: Cambridge Univ. Press.

ecosystems. A diverse set of management practices and social mechanisms from temperate and tropical regions and traditional and contemporary society were identified and analyzed in recognition of their importance for building resilience in combined social-ecological systems (Levin *et al.*, 1998). The focus of the analysis is presented in Figure 1.

The examples stem from a wide range of local resource users, including hunters and gatherers, herders, fishers, agricuturists, and small-scale communities of industrial nations. This article describes these practices in relation to their nature conservation functions. Most of the practices described are interrelated and have multiple ecological functions. Nonetheless, we have categorized them in the manner outlined in Table 1.

As indicated in Table 1, the first category of practices includes ecological monitoring and regulation of the use of biological resources and ecosystems. (see Ecological Monitoring and Practices Framing Access to and Use of Species and Habitats) Section II of this article. The second category mainly concerns traditional agroforestry practices, with an emphasis on their effect for biological conservation. (see Practices of Multiple-Species Management, Resource Rotation, and

Succession). The third category describes management practices that are related to the dynamics of complex ecosystems, in particular the processes that structure ecosystems at different temporal and spatial scales. (see Practices Related to the Dynamics of Complex Ecosystems). Such conservation practices, often at the watershed and landscape levels, are important in securing a flow of natural resources and ecosystem services on which the local community depends.

In the concluding section, we stress lessons that can be learned from traditional conservation practices in building resilience through improved management of biodiversity. Resilience conserves options and opportunity for ecosystem renewal and evolutionary change, and its dynamic maintenance is a prerequisite for all forms of biological conservation.

Ecological Monitoring and Practices Framing Access to and Use of Species and Habitats

The practices described below are often determined by local social institutions. These are often informal, based on traditional norms and conventions. Some appear to be more directly associated with resource management activities, while others appear to be more closely associated with cultural belief systems.

Monitoring the Status of the Resource

Monitoring the status of the resource is very common among local resource users (Folke *et al.*, 1998). Monitoring leads to the acquisition of local ecological knowledge and helps local users respond to resource and ecosystem dynamics. Both qualitative and quantitative indicators develop as the result of experience and ecological knowledge based on monitoring (Johannes, 1998). Monitoring may provide information about location and timing of target resources (i.e., resource procurement) and also the condition and dynamics of individual populations and particular ecosystems for generating target resources. Ecological monitoring also provides the basis for the spatial and temporal regulations of resource use in local communities. Thus, various social response mechanisms evolve as a result of ecological monitoring. These are often in the form of local institutions, such as social taboos, area rotation regulations, and seasonal closures. The list of the importance of ecological monitoring for local resource users can be made very long. We will provide a few examples.

For resource procurement reasons, the Cree of James Bay, Canada, monitor geographic distribution, migration patterns, and individual behavior of caribou, as well as the sex and age composition of the caribou herd, including the presence or absence of predators. They also predict herd size of caribou by examining the fat content of caribou (Berkes, 1998). The Inuit of Quebec and the Inuit and Innu of Labrador also use fat content as an indicator of health of both individual animals and the herd. Such monitoring may provide useful information for resource procurement and in the enforcement of hunting regulations when prey is low in abundance.

Similarly, the Cree of James Bay monitor the interaction between beaver and vegetation (Berkes, 1998). Such monitoring leads to knowledge about beaver populations and their ecological interaction with other biological resources. For example, when aspen is low in a particular area, trappers know that the beaver population is low in abundance.

Knowledge about the effect of natural disturbance regimes on target resources and other species is also based on ecological monitoring. Such knowledge requires monitoring over extensively long time periods and may be passed on from one generation to the next. For example, Cree beaver trappers know that 3–4 years after a fire occurs in an area, beavers will start to inhabit the area again (Berkes, 1998).

Also, monitoring combined with ecological knowledge may lead to resource procurement methods that do not deteriorate the habitats of target resources and secure a sustainable use of target resources. For example, in Tokelau in the South Pacific, islanders use, based on detailed knowledge of octopus behavior, a special octopus stick to extract the animal, which obviates the need for the destructive crushing of the coral or the use of poison (Ruddle, 1994). Another example is the use of the clam rake in the Maine soft-shell clam fishery, which is the only tool allowed for clam harvesting (Hanna, 1998). Such methods reduce the risk that a resource is overexploited, as compared to more advanced forms of technological methods.

Local institutions for management, based on ecological monitoring, may either be permanent in time such as in the two examples above, or “kick in” occasionally in times of resource scarcity. For example, ecological monitoring underlies the Cree’s decision when to rotate beaver trapping grounds and fishing areas. Cree fishers rotate fishing grounds based on a declining catch per unit of effort and rest these sites when needed (Berkes, 1998). In this way, overfishing is limited. Coastal communities in Maine monitor clam populations to help determine the areas needing enhancement (Hanna, 1998). Such response mechanisms represent fine-tuned ways of responding to ecological feedback and are employed in order to avoid overexploitation of subsistence resources.

The widespread uses of closed seasons in Oceania are based on observations founded on local ecological knowledge about the spawning periods of key fish species, and fishing is prohibited during such periods. Pacific island groups often know when and where fish aggregate to spawn. At such aggregation sites, fishers monitor yearly changes of fish stock size and composition and reduce their fishing effort when stocks seem to be low (Johannes, 1978; Hviding, 1988).

Similarly, the use of fishing taboos among Pacific islanders at particular sea areas is based on local knowledge about the

fluctuations of reef fish populations. On Satawal Island in the Central Caroline Island of Micronesia, fishing off one reef section is prohibited by taboo in order to conserve a breeding ground to supply the rest of the reef with resources (Ruddle, 1994). On Tokelau, the *lafu* (fishing taboo) is the most explicit conservation measure. *Lafu* is invoked by the Council of Elders. It bans all fishing in specific areas on the main reef and is announced to permit stock recovery.

Such examples allowing for ecosystem renewal is evident among a number of local resource users. For example, pastoral groups in arid and semiarid Africa monitor ecosystem change by way of tracking to determine daily movements of herds. This includes tracking ecological processes, such as climate, soil content, groundwater availability, forage availability, temporal environmental variability, and environmental degradation. Various forms of indicators are used for this, such as the behavior of fauna, specific plant indicators, soil color and texture, forage quantity and quality, and vegetation/plant composition (Niamir-Fuller, 1998).

Due to the proximity of local resource users to their resource base, ecological monitoring is often feasible on a daily basis. This facilitates detection and response to ecological change. Quite often, monitoring activities may be ascribed to particular individuals in local communities, such as resource stewards, elders, or shamans (Berkes and Folke, 1998).

Total Protection of Certain Species

Total protection of certain species is another practice that is particularly common among traditional peoples. For example, flora and fauna in India have been protected by indigenous belief systems for millennia and have been revered as the vehicles of Gods and Goddesses.

Of particular interest are the different kinds of social taboos imposed on species by traditional societies throughout the World. Colding and Folke (1997) found that specific-species taboos protect threatened species as well as species considered keystone and/or endemic by ecologists. It was estimated that about 30% of the identified taboos protect species listed as threatened by IUCN. Table 2 displays a number of ecologically important and threatened species protected through taboos. This indicates the role that traditional local institutions, such as taboos, may have in biological conservation.

Protection of Vulnerable Life Histories of Species

This practice reduces the danger of overharvesting and the depletion of a population of target resources. For example, in the Maine fisheries, it is prohibited to gather lobsters with eggs (Acheson *et al.*, 1998). Traditional fishing castes in the Bhandara district of Maharashtra, India, never disturb the spawning aggregations of freshwater fish in hill streams, and the Phapsedhis of Maharashtra traditionally let loose pregnant does caught in their snares (Gadgil, 1987). The Cree of James Bay never kill or disturb nesting geese (Berkes *et al.*, 1995). The Tukano Indians of Colombia impose taboos on the collection of bird eggs and avoid the collection of reptiles during their breeding season as well as protect fish spawning

Table 2 Threatened species that are avoided as a result of taboos

Species	Popular name	Local resource users/locality	IUCN status ^a
<i>Kinosternon oaxacae</i>	Oaxaca mud turtle	Pima Bajo, Papago, Yuman, U.S.A./Mexico	I
<i>Chelonia mydas</i>	Green sea turtle	Inhabitants of Buzios Island, Brazil	E
<i>Naja oxiana</i>	Oxus cobra	Local protection in vicinity of temples in India	K
<i>Melanosuchus niger</i>	Black caiman	Piro of Peru	V
<i>Heloderma suspectum</i>	Gila monster	Riverine Pima, Papago, U.S.A./Mexico	V
<i>Pavo muticus</i>	Green peafowl	Tamil Nadu, Rajasthan, Gujarat, India	V
<i>Gorillas gorilla</i>	Gorilla	Edo state, Nigeria	V
<i>Colobus polykomos</i>	Black and white colobus	Villages of Boabeng and Fiema, Ghana	V
<i>Pan troglodytes</i>	Chimpanzee	Edo state, Nigeria	V
<i>Thomomys umbrinus emotus</i>	Southern pocket gopher	Riverine Pima, Papago, Maricopa, U.S.A./Mexico	V
<i>Perognathus alticola</i>	White-eared pocket mouse	Riverine Pima, Papago, Maricopa, U.S.A./Mexico	V
<i>Dipodomys gravipes</i>	San Quintin kangaroo rat	Riverine Pima, Papago, U.S.A./Mexico	E
<i>Dipodomys microps leucotis</i>	Houserock chiseltoothed kangaroo rat	Riverine Pima, Papago, U.S.A./Mexico	K
<i>Canis lupus</i>	Grey Wolf	Bishnois of Thar desert, Rajasthan, India	V
<i>Tremarctos ornatus</i>	Spectacled bear	Achuar of Ecuador/Peru	V
<i>Panthera tigris</i>	Tiger	Local protection in vicinity of temples in India	E
<i>Felis concolor</i>	Puma	Maricopa, Yuman speakers, U.S.A./Mexico	E
<i>Tapirus bairidi</i>	Central American tapir	Coshiro-wa-teri of Brazil/Venezuela; Achuar of Ecuador	V
<i>Myrmecophaga tridactyla</i>	Giant anteater	Coshiro-wa-teri of Brazil/Venezuela; Achuar of Ecuador/Peru	V
<i>Pridontes maximus</i>	Giant armadillo	Achuar of Ecuador/Peru	V
<i>Antelope cervicapra</i>	Blackbuck	Bishnois of Thar desert, Rajasthan, India	V

^aIUCN status: E, endangered; I, indeterminate; V, vulnerable; K, insufficiently known; R, rare.

aggregation sites in rivers (Reichel-Dolmatoff, 1976). Size restrictions are sometimes employed among South Pacific islanders on slow-moving or sessile marine species that are particularly susceptible to over-harvesting (Johannes, 1978).

Protection of Specific Habitats

This practice is commonly found among local resource users. For example, pastoralists of arid and semiarid Africa use buffer zone areas of Sahelian rangelands which are protected from grazing except in the case of emergencies (Niamir-Fuller, 1998).

Also, whole forests, forest patches, coast stretches, rivers, or ponds may to various degrees be protected for human resource use. Usually, such areas are set aside by religious taboos and considered sacred to community members. In India, sacred groves were once extremely common. A sacred grove is a small part of a forest set aside for spiritual or religious purposes. The sizes of such protected areas vary from a clump of 5–10 trees to as much as 50 ha or more (Gadgil and Vartak, 1976). Sacred groves still exist in many parts of contemporary India—for example, in the Khasi Hills in Assam, in the Arvalli ranges of Rajasthan, all along the Western Ghats in the southern peninsula, in the districts of Bastar and Sarguja in Madhya Pradesh, and in the Chanda district in Maharashtra. Gadgil and Chandran (1992) indicate that the Indian traditional shifting cultivation system, *jhum* (described in Practices of Multiple-Species Management, Resource Rotation, and Succession: Management of Succession), is associated with sacred groves.

Kenya has sacred groves all along its coast, known as *kayas* (homesteads), used for ceremonies and burials

(Wilson, 1993). So do the Yoruba of Ara in southwestern Nigeria (Warren and Pinkston, 1998). In South America, the Kuna Indians of Panama have spirit sanctuaries, places where spiritual animals, plants, or demons are believed to reside (Chapin, 1991). According to cosmological beliefs, the Kuna must respect these areas often located on choice agricultural land. The Cocnucos and Yanacunas of Colombia have similar sanctuaries (Redford and Maclean Stearman, 1993). The Tukano of the Uaupés basin on the Brazil–Colombia border reserve the forested river margin for fish and fishing. Fishing may be restricted to as little as 38% of the total river margin available (Chernella, 1987). The result is a management system that allows for, yet distinguishes, human use areas and animal refuge areas. Any deforestation of the river edge is prohibited.

The importance of such cultural beliefs for preserving patches of ecosystems should not be underestimated. New species of plants, and species that have disappeared from other areas, are still being discovered within sacred groves (Mohannan and Nair, 1981). A botanical survey in a Nigerian sacred grove yielded 330 plant species as compared to only 23 in surrounding nonprotected areas (Warren and Pinkston, 1998). Sacred groves are also important for maintaining ecological services, such as preserving local hydrological cycles, preventing soil erosion, serving as firebreaks, and serving as areas of recruitment of species, allowing for ecosystem renewal in face of various disturbances.

Temporal Restrictions of Harvest

This practice is adopted among some local resource users. The idea is that certain biological resources are protected from

exploitation for certain periods of time. Among local resource users, the imposition of temporal taboos regulates access to resource(s) on either a sporadic, daily, weekly, or monthly basis (Colding and Folke, 2000).

For example, clans of Tikopia in the Solomon Islands impose sporadic taboos on particular foodstuffs they are associated with (Chapman, 1985). Several different durations of closed seasons exist among Vanuatu fishing villages, ranging from 1 month to 5 years (Johannes, 1998).

At the Sakumo and Djange Lagoons in Ghana, taboos are imposed on fishing during a particular day every week (Nti-moa-Baidu, 1991). In India, taboos imposed on a monthly basis appear quite widespread. For example, many castes abstain totally from consumption of fish, poultry, and meat, and suspend all hunting as well, in the Hindu month of Sravana (roughly August), which is the peak of the main rainy season over most of India (Gadgil, 1987). Similarly, taboos on hunting certain animals from July to October exist in many Indian villages. The Oraons, the fourth largest tribal group in India, observe a taboo of hunting any wild animal or bird during the months of June and July (Xaxa, 1992).

In Papua New Guinea, the Maopa people in the Marshall Lagoon impose a seasonal ban on hunting (Kwapena, 1984). Every 3–4 years at the end of their cultivation work, a bush area is set on fire to chase and hunt any animals found. This traditional hunting ritual lasts for a week. Once a particular animal-rich area is selected and hunted on, it will be left alone for another 3–4 years. This ritualistic way of hunting allows for hunting areas to regenerate. It may also mimic natural disturbance regimes. Groups of Canadian Amerindian hunters use a similar system for rotating hunting, fishing, and trapping areas by their periodic resting (Berkes, 1998).

In the Maluku Islands of eastern Indonesia, temporal prohibitions on gathering are imposed on terrestrial plant and animal resources, such as coconut, nutmeg, areca, and cuscus, as well as on marine species, including fish, trochus, shell, sea cucumber, and seaweed. This traditional management institution, known as *sasi*, is continually changing, depending on changing social and ecological conditions (Soselisa, 1998).

Locally decided and implemented closed periods is one of the measures used for managing kombu kelp (*Laminaria augusta*) at Hokkaido Island, Japan. Regulations initiated for kelp harvesting as early as 1881 stated that villagers could not harvest kombu in the evening or on a rainy day, when good quality kombu cannot be produced (Iida, 1998).

Practices of Multiple-Species Management, Resource Rotation, and Succession

This category constitutes management practices that largely can be described as agroforestry practices, although hunter and gatherers may employ methods that draw on the same principles. Agroforestry is the generic name used to describe “an old and widely practiced land use system in which trees are combined spatially and/or temporally with agricultural crops and/or animals” (Farrell, 1987). They are common in traditional agricultural systems throughout the world, especially in the tropics, but were once common in temperate regions as well (Beets, 1990).

The three types of practices described in the following are often related to the efficient use of local ecosystems in terms of space, nutrient availability, climatic conditions, and soil conditions. These practices serve to actively manage species diversity and intensity of use of subsistence resources for ecosystem renewal and species recruitment. Such practices often create habitat heterogeneity on the landscape scale, affecting forest structure and species composition by creating a mosaic of forest patches of different ages (Primack, 1993). Thus, the outcome of these practices often enhances diversity of biological resources at the local level (Orejuela, 1992).

Multiple-Species and Integrated Management

The cultivation of several species of crops on the same piece of land is often referred to as polycultures or intercroops. There is an enormous variety of this type of practice, and they may involve the mix of annual crops with other annuals, annuals with perennials, or perennials with perennials. Crops may be sown in different spatial arrangements and may range from the growing of two crops in alternate rows to complex assemblies of a dozen or more species (Altieri, 1987). Integration of crop cultivation with animal species is also common in traditional agroforestry systems.

Polyculture cropping systems constitute at least 80% of the cultivated area of West Africa and predominate in other parts of Africa as well as in the Latin American tropics and many Asian countries (Liebman, 1987). Frequently, more yield can be harvested from an area sown in polyculture than from an equivalent area of monoculture without the application of synthetic fertilizers, pesticides, and field machinery. Polyculture cropping systems may provide several social–ecological benefits as compared to monocultures (Liebman, 1987)—for example, by reducing the risk of total crop failure and by contributing to an increase of nutritional returns to local resource users.

Polycultures may also promote soil water conservation and nutrient recycling as well as reduce soil erosion and insect pests. Some polyculture systems may also reduce crop diseases and increase weed control. Polycultures may thus provide for many ecological services, including the maintenance and enhancement of biological diversity. In fact, diversity is used to enhance productivity and resilience (Berkes *et al.*, 1995).

The two most common polyculture systems in Java, Indonesia, are *Talun-kebun* (rotation between mixed gardens and tree plantation) and *pekarangan* (home garden intercropping system including animals) (Altieri, 1987). A *Talun-kebun* is an indigenous Sudanese agricultural system, consisting of three stages that each serves a different function. In the first stage, *kebun*, a mixture of annual crops is usually planted, mainly for cash income. After 2 years, tree seedlings begin to grow in the field, and the *kebun* gradually evolves into a *kebun-campuran*, where annual crops are mixed with half-grown perennials. This stage promotes soil and water conservation. After the annuals are harvested, the field is usually abandoned for 2 or 3 years and becomes dominated by perennials, the *talun* stage (perennial crop garden). The *talun* can be turned back into a *kebun* after the forest is cleared or be planted to rice paddy, depending on whether irrigation water is available.

A *Talun-kebun* may be composed of up to 112 species of plants, of which about 40% provide for building materials and fuel wood, 20% are fruit trees, 15% are vegetables, and the remainder is used for ornamentals, medicinal plants, spices, and cash crops (Altieri, 1987).

The integration of animals in polyculture systems is a common practice in diverse regions of the world. In Southeast Asia, rice ecosystems include diverse animal species. For example, domestic ducks may be integrated in paddy rice cultivation to allow for insect and weed control, and fish species, such as common carp, may be integrated and harvested at the end of the rice-growing season. The rice/fish culture differs considerably from country to country and from region to region (Altieri, 1987).

In China, as in Southeast Asia, crops, chicken, duck, and fish are often integrated to provide for a very high overall production through waste recycling and use of residues (Yan and Yao, 1989). Also, natural control of insects and weeds is provided for in these systems (Beets, 1990). In Indonesia, traditional systems combined rice and fish culture, and wastes from this system often flowed downstream into brackish water aquaculture systems (*tambak*). The *tambaks* were polyculture ponds, often combining fish, vegetation, and tree crops (Gadgil *et al.*, 1993).

In Rajasthan, India, local farmers grow crops and rear livestock under and among trees. The Bishnoi, inhabiting one of the driest climatic zones on Earth, integrate the cultivation of food crops and animal rearing among islands of khejri trees, *Prosopis cineraria*, which are strongly protected by religious taboo (Sankhala, 1993). The Bishnoi keep as many khejri trees as possible on their farms, providing them with material for fencing, firewood, and fodder and pods for cattle as well as providing excellent microclimatic conditions for crop cultivation. Even threatened species, such as the blackbuck and gray wolf, benefit from these farming systems (Colding and Folke, 1997).

In many parts of Africa, "farm trees" can also be found within and adjacent to farm fields. The trees are actively protected, harvested, and managed by farmers to yield construction poles, fuel wood, fodder, edible fruits, nuts and leaves, medicines, and other products without unduly competing with associated annual crops (Beets, 1990).

Resource Rotation

Resource rotation exists among several communities of local resource users (Folke *et al.*, 1998). Chisasibi Cree hunters rotate trapping areas (ideally) of beavers on a 4-year cycle to allow for the recovery of beavers to these areas. They use a similar rotational practice for resting fishing areas, using a traditional pattern of fishing in remote lakes on a 4- or 5-year cycle. Also, Cree goose hunters rotate hunting areas on a 7-day cycle in order to reduce disturbance to feeding and resting geese and to harvest for subsistence needs with a minimum disruption of the large population that passes through an area (Gadgil *et al.*, 1993).

The Awa Indians of southwestern Colombia and neighboring Ecuador hunt echimid rodents on a cyclical basis, which allows sufficient time for the recovery of wild populations (Orejuela, 1992).

Arid and semiarid African pastoralists migrate seasonally in accordance with plant availability, determined by precipitation and lunar cycles (Niamir-Fuller, 1998). The yearly cycle of nomads and their cattle provides a rotational management system that enables the recovery of heavily grazed rangelands. For example, the Wodaabe Fulani follow the lunar cycle when moving to new pastures, which means that the camp is moved every 2–3 days. By contrast, the Rufa'a al Hoi of Sudan move to a new pasture every 204 days. The Fulani of northern Sierra Leone once practiced "shifting pasturage," whereby they heavily stocked an area for 2–3 years and then moved elsewhere and rested the first area for 15–20 years. These are all examples of small-scale movement, or micromobility, practiced by many Sahel pastoralist tribes (Niamir-Fuller, 1998). Local resource users enforce grazing rotation in parts of the Hindu-Kush Himalayas in a similar fashion (Jodha, 1998).

Management of Succession

Polycultures and crop rotation often involve management of succession, as exemplified by the different systems of shifting cultivation that exist in the world. Shifting cultivation is defined by FAO (1982) as "a farming system in which relatively short periods of cultivation are followed by relatively long periods of fallow." Although part of polycultures, it can be distinguished by fallow periods that are ideally very long.

Shifting cultivation, or "slash-and-burn" cultivation or "swiddens," involves the clearing of a plot of land, usually a forest area, its use for a few years, and, as soil fertility declines, its abandonment in favor of another plot of land to be cleared in the same fashion. It is one of the oldest forms of agriculture and most present-day agricultural systems have evolved from it. In shifting cultivation, agriculture becomes a sequential cropping of crops and noncrops. Presently, about 3–500 million people, or about 40% of the total agricultural population of developing nations, depend on shifting cultivation for their daily livelihood. In total, shifting cultivation covers about 30% of the world's exploitable soils (Beets, 1990).

Shifting cultivation is common in all tropical areas and was once common in temperate regions as well. It has received much attention as one of the major degrading processes in tropical forest areas due to human population increase that greatly has led to shortages in fallow periods with subsequent loss of soil fertility. Generally, if fallow is less than 5–7 years, land degradation occurs and species diversity may be greatly reduced (Berkes *et al.*, 1995). However, if adequate long fallow is allowed for, shifting cultivation may be highly sustainable (e.g., Posey, 1985).

Extremely high crop diversity is a characteristic of many traditional shifting cultivation systems. For example, Philippine swidden cultivators can distinguish over 600 plant species (Beets, 1990). In general, swiddens do not compare in complexity to the surrounding forest. However, when shifting cultivation is analyzed as an agroforestry system, i.e., the use of trees is also taken into account, then the overall result of managing forest patches can lead to an enhancement of biodiversity (Berkes *et al.*, 1995). For example, the Runa Indian managed swiddens in the Ecuador Amazon increase species diversity in 5-year-old fallows as compared to unmanaged

Figure 2 Among the Kayapo Indians of Brazil, enhancement of biodiversity is facilitated by the creation of forest islands, *apete*. Through a number of management methods, this behavior promotes patchiness and heterogeneity in the landscape in time and space. Reproduced from Gadgil M, Berkes F, and Folke C (1993) Indigenous knowledge for biodiversity conservation. *Ambio* 22: 2–3.

fallows. Between 14 and 35% of this enhanced species diversity was attributed to direct planting and protection of secondary species.

Different forms of swiddens and related fallow systems exist in the world. In tropical Mexico, as well as in other Mesoamerican countries, *milpa* (maize fields) is widely practiced (Alcorn and Toledo, 1998). *Milpa* involves the clearing of new fields in high forests, or secondary regrowth forests, for maize cultivation. If more than one successive crop of maize is taken in a short fallow *milpa*, weedy species come to dominate the plot and forest regeneration may not occur. *Milpa* is governed by strong informal institutions, which reinforces reciprocity and community-based control of natural resources. Farmers who mismanage their *milpa* are labeled as witches and punished by social pressure. Each stage of the *milpa* cycle is also named and marked by ritual activities, rendering *milpa* a strong sociocultural practice.

The Awa Indians of southwestern Colombia and neighboring Ecuador practice a shifting agriculture known as slash-mulch (Orejuela, 1992). It involves the cutting of natural vegetation and the mulching of this material for a temporary agricultural field. Maize and/or short-cycle varieties of red and white beans are planted by the slash-mulch method. Once yields decline after several cycles of harvest, the field is left fallow and permitted to regrow as an enriched secondary forest. A similar system involving mulching is used to clear lots to raise cattle.

In northeastern India, detailed studies on shifting agriculture (*jhum*) have described multispecies systems involving 4 to over 35 crop types based on locally adapted native strains (Berkes *et al.*, 1995). This practice requires sophisticated local ecological knowledge, including the use of soil nutrients by adequate changes in the crop mixture depending on the length of *jhum* cycles and the consequent availability of soil nutrients. On hill slopes, farmers combine r-strategist species (cereals and legumes) with K-strategists, with emphasis on vegetative growth, such as leafy vegetables (Berkes *et al.*, 1995).

An interesting form of shifting cultivation by the Kayapo Indians of Brazil constitutes the creation of forest islands known as *apete* (Posey, 1985). This begins as small mounds of

vegetation about 2 m in diameter (*apete-nu*). As planted crop and tree seedlings grow and the planted area expands, the taller vegetation in the center of the mounds is cut to allow light to enter. A full-grown *apete* has an architecture that creates zones that vary in shade and moisture (Figure 2). The species mix includes medicinal plants, palms, and vines that produce drinking water. Of a total of 120 species found in 10 *apete*, Posey (1985) estimated that 75% may have been planted. *Apete* constitutes the manipulation of semi-domesticated plants on which the Kayapo could survive during times of warfare. These old forest islands have been scattered for millennia in known spots throughout the forest and savanna.

Practices of multiple species, resource rotation, and succession management contribute to biodiversity conservation relative to more modern and technology-dependent ways of exploiting resources and ecosystems. By actively using biodiversity in production, they contribute to biodiversity conservation in areas outside protected areas and reserves.

Practices Related to the Dynamics of Complex Ecosystems

Apete is also a good example of traditional practices that actively promote patchiness and heterogeneity at the landscape level. Many agroforestry systems make use of patchiness for multifunctional benefits, although patchiness may also be used in smaller cultivation systems to provide for crop protection and natural pest management (Altieri, 1987).

Management of Landscape Patchiness

Such management is employed by Sahelian pastoralists in order to mimic the variability and unpredictability of the landscape. For example, an appropriate mix of herding animals is used to utilize different vegetation types and patches in a dynamic fashion (Niamir-Fuller, 1998). The progressive widening of grazing radius around wells as the wet season

advances is also an example of active management at the landscape level. This practice is employed by the Maasai of Kenya to leave enough forage around wells for the dry season (Niamir-Fuller, 1998).

Fire management among Australian aborigines and northern Canadian Amerindians was practiced widely to open up clearings (meadows and swales), corridors (trails, traplines, ridges, grass fringes of streams and lakes), and windfall forests. These clearings provided improved habitats for ungulates and waterfowl, thus increasing hunting success, and the corridors and windfall areas improved accessibility (Gadgil *et al.*, 1993).

The use of different elevation zones for cultivators in the eastern Himalayas and other parts of the world represents practices that make use of habitat heterogeneity and create patchiness at the landscape level. The ancient *ahupua'a* system of Hawaii utilizes different elevation zones, determined by precipitation, that are used for various integrated farming practices (Costa-Pierce, 1987). In the ancient *ahupua'a*, both freshwater and seawater fish ponds were integrated with agriculture, and river valleys were managed as integrated systems, from the upland forest (left uncut by taboo) all the way down to the reef (Costa-Pierce, 1987).

Watershed Management

The *ahupua'a* also constitutes an example of traditional watershed management systems. Southeast Asia and Oceania had, and to lesser extent still have, a number of these pre-scientific ecosystem management practices. Examples include the Yap *tabinau*, the Fijian *vanua*, and the Solomon Islands *puava* (Ruddle *et al.*, 1992). These all refer to generically similar watershed-based management systems. For example, the *vanua* concept is an integrated human–nature component that regards the land, water, and human environment as one unit, one and indivisible (Ruddle *et al.*, 1992). Similarly, the *puava* includes all resources and land in a watershed, from the top of the mainland mountains to the open sea outside the barrier reef (Hviding, 1990). In all these cases, the social group inhabiting the ecosystem unit is considered to be part of the system.

Managing Ecological Processes at Multiple Scales

There is some evidence that traditional management systems may be useful in managing ecological processes at multiple scales. In *milpa*, (described earlier in Practices of Multiple-Species Management, Resource Rotation, and Succession: Management of Succession), food crops are managed on a 1- to 3-year scale, and some tree crops and products on a 30-year scale (Alcorn and Toledo, 1998).

James Bay Cree hunters seem to be simultaneously managing beaver populations on a 4- to 6-year scale, lake fish on a 5- to 10-year scale, and caribou on an 80- to 100-year scale (Berkes, 1998). The holistic forestry of the Gitskan people of northern British Columbia simultaneously manages the production of fiber over several square kilometers with ecological processes involving soil bacteria at the spatial scale of a few square meters (Pinkerton, 1998).

Responding to and Managing Pulses and Surprises

Natural disturbances, such as fire, hurricanes, pest outbreaks, and heavy grazing, are inherent to the internal dynamics of ecosystems and often set the timing of ecosystem renewal processes (Holling *et al.*, 1995).

An example of a practice that responds to disturbance and manages pulses and surprises is the establishment of range reserves within the annual grazing areas of African herders. These reserves provide an emergency supply of forage that serves as buffer when disturbance, such as drought, challenges the process and function of the dryland ecosystem (Niamir-Fuller, 1998). At the landscape level, this functions to maintain the resilience of both the ecosystem and the social system of the herders. Such practices may be considered ecological adaptations to unpredictable, low-rainfall environments and provide “ecological insurance” to the local communities.

Sacred groves in India absorb disturbance by serving as firebreaks for cultivated areas and villages (Gadgil *et al.*, 1998). At the same time, these sacred habitats function as recruitment centers for species regeneration and ecosystem renewal. In times of natural disturbances and other emergencies, such areas of refugia are essential for providing social–ecological resilience.

Many of the traditional forms of polyculture previously described may provide for pest and insect protection that contributes to building resilience (Altieri, 1987). The Warlis of India control pests by placing certain kinds of tree branches in their paddy fields. This practice serves to attract birds for insect control and buffers against outbreaks of various pest populations (Pereira, 1992).

Nurturing Sources of Ecosystem Renewal

Many traditional societies seem to actively nurture sources of ecosystem renewal by creating small-scale disturbances. Traditional agroforestry practices such as shifting cultivation create forest gaps and enable people to produce crops or enhance wild foods without disrupting natural renewal processes (Berkes *et al.*, 1995). Such practices may even enhance genetic and ecological diversity in the benign mosaic landscape of forest, fallow, and gardens (Orejuela, 1992). Also, traditional rotational cycles employed by hunters and gatherers, (described in Practices of Multiple-Species Management, Resource Rotation, and Succession), allow for species recovery of wild populations.

Aboriginal use of fire in as geographically diverse areas as Canada, Australia, and California had many elements and principles in common (Berkes *et al.*, 1995). Until the late 1940s, Amerindians of northern Alberta, Canada, regularly used fire to create clearings (meadows and swales), corridors (trails, traplines, ridges, grass fringes of streams and lakes), and windfall forests (Lewis and Ferguson, 1988). These clearings provided improved habitat for species such as ungulates and waterfowl. Australian aborigines possessed detailed technical knowledge of fire and used it to improve feeding habitat for game and to assist in the hunt itself (Lewis, 1989).

African herders behave like a disturbance by following the migratory cycles of the herbivores from one area to another

(Niamir-Fuller, 1998). Pulses of herbivore grazing contribute to the capacity of the semiarid grasslands of Africa to function under a wide range of climatic conditions. If this capacity of the ecosystem to deal with pulses is reduced, an event that previously could be absorbed can flip the grassland ecosystem into a relatively unproductive state, dominated and controlled by woody plants for several decades (Walker, 1993).

Concluding Remarks

One of the 10 principles of the *Global Biodiversity Strategy* concerns the linkage of biodiversity with cultural diversity and the conservation of the two together. At a broader level, traditional conservation practices as a part of cultural diversity may offer benefits in terms of local biological and ecological understanding, sustainable resource management systems, implementation of protected areas, development planning, and environmental impact assessment. Each of these potential benefits is related to biodiversity conservation, either directly or indirectly. Biodiversity is recognized as an important component of sustainable use. It is in this sense it is being conserved through traditional conservation practices as illustrated in this article through practices framing access to and use of species and habitats, practices of multiple-species management, and practices related to biodiversity conservation in complex dynamic ecosystems. Such practices seem to contribute to maintaining and building ecological resilience *sensu* Holling (1986).

Traditional conservation practices rely on the accumulation of ecological knowledge and understanding over many generations, and knowledge is embedded in local institutions and transmitted culturally. Practices are generally site and context specific although the ecological knowledge embedded in them may be spatially and temporally transmitted.

The locally generated knowledge and associated conservation practices are not necessarily complete in the sense of understanding of all aspects of an ecosystem and its dynamics. However, many traditional conservation practices are in line with the shifting scientific view on the nature of ecosystems as nonlinear, multiequilibrium, and full of surprises, threshold effects, and system flips. Predictability and controllability are not limited by the scientific data available but by the very nature of ecological systems.

Traditional ecological knowledge systems, based on detailed observations of the dynamics of the natural environment, feedback learning, social system–ecological system linkages, and resilience-enhancing mechanisms, seem akin to adaptive management (Berkes and Folke, 1998). Traditional conservation practices parallel adaptive management in their reliance on learning-by-doing and the use of feedback from the environment to provide corrections for management practice.

The parallels between adaptive management and indigenous management systems are probably not accidental. Flexible social systems that proceed along by learning-by-doing are better adapted for long-term survival than are rigid social systems that have set prescriptions for resource use. In light of this, adaptive management in modern society could be seen as

a replication of traditional ecological knowledge systems in the framework of contemporary science. It is a sort of re-discovery of principles applied in traditional social–ecological systems. It is a search for sustainable use of ecosystems and biological diversity as a means of survival, a social and institutional response to resource scarcity and management failure. Even though there are no doubt major differences between the two, adaptive management may be viewed as the scientific analogue of traditional ecological knowledge and practices because of its integration of uncertainty into management strategies and its emphasis on practices that confer ecological resilience.

Glossary

Captive breeding Collection of organisms from nature followed by human husbandry to maximize the reproduction and survival of an organism of interest, usually in a zoo, botanic garden, or other controlled environment.

Conservation Steps taken by people to preserve the diversity of life on Earth and the health of natural ecosystems, usually to counteract a force that erodes or reduces natural processes.

Introduction Placement of individual organisms by people into a habitat for purposes of establishing a population in a place where it does not currently occur.

Managed relocation Intentional movement by humans of organisms from a place where that organism lives currently to a new region where it is likely to persist in the future due to human-caused climate change.

Reintroduction The placement of individual organisms by people into a habitat for purposes of establishing a population where a previous population has gone locally extinct.

Supplementation The purposeful introduction of additional organisms to an existing population to increase mean fitness or population size.

Translocation The intentional movement of organisms by people from one or more locations to other locations.

Overview of Translocations for Conservation

Humans have exploited nature and its creatures for thousands of years. But as threats to nature from pollution, over-exploitation, invasive species, and other side effects of human civilization emerged, people began to worry about the protection of nature. And they began to take steps to conserve organisms and ecosystems for future use. This intervention to prevent the decline of nature involves many tools and strategies, including the movement of seeds, shoots, and animals from one location to another. This *translocation* of organisms has a long history because economic, social, and even accidental reasons compel us to pick things up and deposit them somewhere else. This article discusses why and how people move organisms, and sometimes entire populations, to advance the cause of conservation. It is informed by the successes and failures of past translocation efforts, and it raises new reasons why translocations may play an increasing role in conservation planning in the future. Translocations for conservation are rarely a panacea because they usually address conservation problems for an individual species in a specific location, but they can be a powerful tool that may work when other conservation strategies fail. In recent years, translocation has reemerged as an active topic of debate, and still more research can shed light on the appropriate and inappropriate uses of translocation for emerging conservation objectives.

Translocations in Traditional Conservation

Conservationists are people who work to reduce the social, economic, and environmental factors that diminish natural ecosystems. To *conserve* is to retain something as it was before, to prevent it from disappearing or declining. Conservationists include park and wildlife managers, nongovernmental organizations, landowners, and private citizens, and they use a number of tools or techniques to achieve their goals.

Conservationists can, for example, remove a threat or stressor to an ecosystem through pollution control or invasive species removal; they can restore an ecosystem through cleanup and species planting; and they can set aside land or water to be left untouched by humans. Sometimes they might even move species from one area to another to restore a native habitat, to save a species from extinction, or to enable genetic mixing and reduce negative effects of inbreeding in small populations.

Conservation biologists are scientists who study the process of conservation and the strategies that humans can use to sustain nature and help it flourish. Conservation biologists evaluate the effectiveness of conservation techniques, suggest ways to achieve conservation goals, and point out where conservation intervention is needed because natural resources are declining. The consultation of conservation biologists is critical to designing conservation interventions that help, rather than undermine, the cause of preservation. Just like conservationists, conservation biologists have long been interested in understanding the costs and benefits of moving species to achieve conservation goals.

Conservation biologists divide the various ways of moving species into categories based on whether the movement (1) is reconstructing some past condition, (2) is to an already-occupied locality, or (3) is to a new location. All of these movements can be called *translocations* because they require picking an organism up from one area and putting it in another. Some translocations involve seed storage or captive breeding that separates the stages of collection and deposition, but all organisms come from an original source population because we cannot create nature from anything other than nature itself.

Reintroductions involve moving organisms from an area of current occupancy to areas where historic populations became locally extinct. Reintroductions are critical to restoration — the reconstruction of a habitat to some historic state. For example, as nearly all of the native tallgrass prairie in Wisconsin, Iowa, and Illinois was converted to agriculture, scientists at the University of Wisconsin with help from the Civilian

Conservation Corp initiated the first prairie restoration in 1936 (Allison, 2002). Since then, prairie planting and restoration has become one of the only ways that diverse prairie habitats exist in the Midwest, providing habitat for animals, cycling nutrients, cleaning storm water, and taking up and storing carbon. Most restorations use locally sourced seed so that historic genetic structure can be maintained or replicated, and attempts are made to create communities that are historically accurate. Re-introductions are also an essential tool of endangered species management. One of the most famous examples of single-species reintroduction is the California condor. When two captive-bred birds were released in 1987, they represented a culmination of 14 years of research and breeding worth \$20 million (Cohn, 1993). Today, there are more than 100 condors living in the wild, though the species remains on the list of critically endangered species. Though primarily consumers of carrion, condors are similar to other restoration projects that restore diminished ecosystem functioning through re-introduction of top predators. These predators exert control on large herbivores and thereby encourage greater ecosystem productivity (e.g., see Ripple and Beschta, 2004).

Supplementation is the addition of organisms to an existing population. Fisheries and timber managers often supplement existing populations to increase the number of sport fish or the quantity of board feet. Supplementation can also be used to introduce genetic diversity into an existing population where that diversity will help the population expand or persist for a longer period of time. For example, eight panthers from Texas were introduced into south Florida in the mid-1990s to reduce inbreeding depression in the declining Florida panther. Subsequent studies found that kittens born to Texan mothers and Floridan fathers had a higher survival to adulthood than purebred cats (Pimm *et al.*, 2006). This benefit may explain recent increases in the abundance and habitat use of Florida panthers that appears to have staved off imminent extinction.

Introductions involve the placement of organisms into a new area, generally where a species has not occurred historically. Introduction has been a rare occurrence in conservation and natural resource management because most scientists feel that placing species where they have not occurred previously can be damaging to other species. In some cases, introductions have been pursued near a species' historic range where habitat is sufficiently similar and introduced populations can flourish. This is the case for Tule elk introduced to Owens Valley of California, for example, where a rare subspecies was placed in an area east of its historic range. Some species also have been introduced to escape a threat that exists in their historic range. This was the case for koala that were introduced to islands in Westernport Bay, Victoria, in the late 1800s and early 1900s to avoid threats of hunting, disease, and habitat loss in their native mainland range (Short and Smith, 1994). These introductions were later used as a source for reintroductions back to mainland Australia, where local populations had gone extinct.

Emerging Motivations for Translocation

This broad role for translocation in traditional conservation, to restore and preserve biodiversity, serves as a backdrop for new ideas about translocation. This time it could be used to

combat worldwide shifts in several environmental conditions. For one, climate strongly affects where species live, and climate change causes populations to expand into new areas and disappear from others. In addition, human activities, such as the addition of fertilizers are pushing communities into altered states with differing species composition and differing system functioning. Human populations also continue to grow, increasing stress on rural areas to provide food and other services such as timber, minerals, and freshwater; and massive tropical deforestation continues at an alarming rate, threatening the heartland of global biodiversity.

Each of these factors – global climate change, nutrient application, land-use change, and human population growth – are changing the “baseline” of life on Earth. They make it increasingly difficult for conservationists to achieve the objective of preserving (or reconstructing) nature as it used to be. These factors of global environmental change are, in fact, undermining the very definition and objectives of conservation and conservation biology. We will need to substitute a new, evolving definition of conservation that is forward-looking and works to maintain biodiversity as it shifts due to human forces. Scientists, governmental agencies, stakeholders, and the public are not finished grappling with a new interpretation of conservation biology, but possible objectives include maintaining as much global biodiversity as possible (e.g., genetic, species, and habitat diversity) and maximizing ecosystem services such as flood control, nutrient cycling, and aesthetic values. Perhaps an ethic of sustainability will emerge in conservation biology, where natural resources are available for future generations to enjoy as much as they have been enjoyed by previous generations, but the identity of those resources changes steadily over time. In this way, ecosystems are preserved not as they have been but as they can be – in a dynamic state that is often managed by people to maintain diversity and function.

In this new paradigm of conservation where future ecosystems are “preserved” in a dynamic, active way, an expanded role for translocations may appear. For example, species might be moved from areas where they historically lived to new areas so that they do not go extinct due to climate change. Species might also be moved to new areas because changing conditions have enabled a service-delivering species to live in a new area where it can provide a valuable ecosystem function such as purifying water or controlling floods. Organisms might also be moved within a range to introduce new genotypes to existing populations, genotypes that are resistant to warmer temperatures or climatic extremes. Other translocations could be imagined to combat other forms of environmental change – such as habitat loss due to large-scale hydropower development or habitat incursion from human refugees that are escaping sea-level rise or extreme drought. Translocation for these purposes have not yet been articulated or named, but we can look forward and imagine their possible use.

Consider the example of the island scrub Jay that lives only on Santa Cruz Island off the California coast. The species is not listed as threatened or endangered, but we can anticipate future threats from emerging disease such as West Nile virus, rising sea levels, changing habitat from climate change, and small population size. Morrison *et al.* (2011) suggest that an

integrated strategy include captive breeding, vaccination against West Nile, and introduction onto a second island to increase population size and spread the risk of local extinction. Such integrated strategies, including translocations for new population establishment, may become standard practice for precautionary species management.

Managed Relocation

Though translocation may play several roles in a world dominated by global change, at least one role has been recently named and explored in the literature. This idea was first termed *assisted migration* to describe how humans might help species “migrate” from one location to another as the climate changes. Avoiding the potential for policy makers and the public to misinterpret migration, this idea also has been called *assisted colonization*. This term has been criticized, however, because *colonization* only allows for population establishment and not persistent tending, monitoring, and even removal in the event of unanticipated, negative outcomes. Most recently, the term *managed relocation* was coined to imply a suite of activities that one might do to place a species in a new location and manage it there once it has established. Managed relocation was defined by Richardson *et al.* (2009), arising from an international working group formed to study the pros and cons of the idea. It is an “intervention technique aimed at reducing negative effects of climate change on defined biological units such as species, populations, or ecosystems. It involves the intentional movement of biological units from current areas of occupancy to locations where the probability of future persistence is predicted to be higher.” The lack of personality in this terminology, however, is a significant downside when explaining the idea to the public. It remains to be seen which term will stick; likely, multiple terms will be used in differing contexts.

There have been very few examples of managed relocation to date, but new conversations about it are arising all of the time. A few studies have examined the process of population establishment in areas outside a species’ range through experiments that test the viability of managed relocation (e.g., Marsico and Hellmann, 2009; Willis *et al.*, 2009). Some citizen groups concerned with the preservation of particular species also have moved organisms to new areas (e.g., *Torreya taxifolia* via the Torreya Guardians, a not-for-profit group). As of 2011, no managed relocation activities were being officially pursued by regional or national governments, though the issue is being deliberated as agencies grapple with the management implications of climatic change.

Factors Determining Translocation Success

Whether the motivation for translocation is classic conservation or in response to modern global change, a number of factors have been identified that increase the success of population establishment (Griffith *et al.*, 1989; Wolf *et al.*, 1996). In the case of animals, for example, Fisher and Lindenmayer (2000) identified the following as increasing the chances of successful translocation: (1) removal of the original

reason for population decline in the case of reintroduction; (2) using wild stock, as opposed to stock that was bred in captivity, whenever possible; (3) including as many individuals in the translocation as possible; and (4) considering nonecological factors such as public relations, participation by a reputable agency or actors, and the long-term commitment of stakeholders and other parties. These factors should prevent subsequent declines (1 and 2), reduce the need to perform the translocation multiple times (2), minimize genetic bottlenecks (3), and maximize social acceptability (4). We need additional research on the factors determining the success of translocations for a wider range of taxonomic groups to inform best-practice guidelines, however (Milton *et al.*, 1999). In addition, social scientific research is critical to examine when people value translocations and when they do not, particularly if translocations expand as a conservation tool as in the case of managed relocation.

Risks and Costs of Translocation

Although translocation may sometimes be a valuable conservation approach, it also comes with significant downsides. The risks of translocations are magnified by the complexity of nature and our relative lack of understanding about the processes that control nature. The implementation of translocation can also be very costly, particularly if it is employed in a thoughtful way using risk assessment and experimental research to guide the implementation process.

The first problem with translocation is the risk of overexploitation to source populations. Even if a captive breeding program is used to maximize the number of introduced individuals and minimize taking from natural populations, nature is the ultimate source of all translocation material. If a species or population is highly threatened, then the removal of even a small number of individuals could increase the risk of local (or global) extinction or increase the risk of inbreeding or other genetic problems of small populations. If a translocation fails to establish, then multiple extractions from a source population might be necessary. This risk of overexploitation has caused some to suggest that highly endangered species should not be targets for managed relocation, for example.

The second problem is that translocations run the risk of creating pest or nuisance populations where they are introduced. Even where a species has been reintroduced where it occurred historically, the ecological and social context of that ecosystem may have changed so that the introduced species is now considered harmful, as in the case of some ranchers perceiving reintroduced wolves as nuisance predators. In the case of managed relocation, introduced species could reduce the abundance of other species in the introduction area, risking local extinction of native species and altering ecosystem function and community composition. To explore this risk, a recent paper built a database of current invasive species in North America and assumed that invasive species with a North American origin are useful analogs for cases of managed relocation (Mueller and Hellmann, 2008). The authors found that the overall risk of invasion from species moved within North America was relatively low; approximately 14% of all

Figure 1 Percentage of species invasive in North America that originate from elsewhere in North America, according to a database of invasives assembled by Mueller and Hellmann (2008). These species of “intracontinental origin” are analogous to species that might be translocated poleward to minimize biodiversity losses due to climate change (i.e., managed relocation). In some taxonomic groups (e.g., plants), a small percentage of currently invasive species come from within North America, but in other groups the percentage of invasive forms of nearby origin is quite high (e.g., fish). In these later cases, translocations under climate change could have a high likelihood of creating nuisance species.

invasive species in the database came from within North America. However, these 14% of species were just as likely to be rated as very harmful in terms of ecological impact as they were likely to have low or minimal impact. Further, the risk of intracontinental invasion was considerably higher in some groups than others, with as many as 50% of invasive freshwater fish species having a North American origin, for example (Figure 1). These findings suggest that the overall risk of creating nuisance species via managed relocation could be low or infrequent, but the activity could be ill-advised for some species and will undoubtedly be damaging in some instances.

The counterargument to the risks raised and explored by Mueller and Hellmann (2008) is that invasive species are not representative of organisms that might be moved via managed relocation or other kinds of intracontinental translocations. For example, rare or endangered species that might be helped via managed relocation may be less likely to become nuisance species than those species already identified as invasive and thus included in the Mueller and Hellmann (2008) database. Still other researchers point out, however, that our understanding of the factors that cause a species to become a nuisance are not well known. More sophisticated risk analyses for managed relocation in particular species and taxonomic groups is needed. Social science and legal research also is needed to shed light on who might bear responsibility for damages due to translocations when they occur. These damages might not always be ecological or economic in nature; they also could include a degradation of cultural or social

values for people with established ties to the region or ecosystem where a translocation takes place.

A third risk of translocation is hitchhikers or incidental introductions that can inadvertently happen during a translocation. Consider, for example, a pest insect or disease that might accidentally be introduced on an endangered plant moved via managed relocation. In these instances, quarantine measures followed by zoos in captive-breeding programs should be followed by land managers considering translocation, especially if translocations become more widespread due to increasing global change.

Finally, economic costs of translocations vary widely (Lindburg, 1992), depending on the extent of habitat preparation, captive breeding, ease of obtaining source material, and other factors. If the number of translocations increases in the future, then the total costs of the activity could be considerable, possibly outweighing the costs of dealing with the causes of global change directly. For example, if translocation becomes necessary to conserve a large number of species and ecosystems in the face of climate change, then it could be more costly than reducing greenhouse gas emissions. Litigation that might be associated with translocations could push costs higher.

The Ethics of Translocation

When humans move organisms from one location to another – whether in an attempt to recreate nature or to enhance its future function – we are tinkering with nature. This comes with a number of possible benefits and risks as described above, but it also comes with important ethical and moral considerations. These moral and ethical dilemmas strike at the heart of humanity’s relationship with nature. Some people believe that nature exists to service humankind and that proper management and wise use are the core values of conservation. Others think that humans must be responsible stewards of nature based on more than just self-interest — that stewardship comes out of respect for a creator, the power of nature, or the astonishing process of evolution that has produced life as we know it. Still others think that the proper place for human society is outside of nature altogether, such that wilderness and wild spaces are best left untouched by humans. Each perspective can lead to a different evaluation of translocation.

As profound changes to the global environment occur, we must confront difficult ethical questions. For example, do we bear moral or ethical responsibility for stress or death to translocated organisms in terms of animal welfare (e.g., see Singer, 1975)? Or is the preservation of a species or a genotype a sufficient objective? Is it appropriate to try to undo the effects of climate change by further interfering with environmental processes via managed relocation, or is it arrogant to think that humans could correctly engineer systems under climate change (Minteer and Collins, 2010)? Are we morally and ethically obligated to minimize the effects of climate change on biodiversity because we caused the problem in the first place? Exploring the ethical issues of translocation can help society envision the future that we want and the kind of nature that we hope to keep for future generations.

Conclusions

The idea that humans should work to preserve the functioning of ecosystems and the genetic diversity that makes up nature is well established socially and scientifically. How best to achieve these goals, however, is not always clear. A diverse set of tools are available to conservationists, and one of these tools is translocation – the purposeful movement of organisms from one location to another. Many translocations for conservation have been successful in that they preserve biodiversity with minimal negative side effects. Nonetheless, the fear of unintended consequences form a constant backdrop for translocation, as do nontrivial economic costs. It is unlikely that we can anticipate all of the potential risks and costs of translocation at any time in the future given the complexities of natural systems and human values.

We must increasingly recognize that few ecosystems and habitats remain untouched by humans, and the power of humanity to transform nature is profound. Translocations may be a tool for reducing some of those ecological and social damages. As we reevaluate the objectives of conservation and shift from a reconstructive and historic-looking perspective to one of dynamic shifts and change caused by humanity, our views on translocation will undoubtedly grow and change. New research is needed that evaluates translocation for conservation purposes and produces the best practices for multiple taxonomic groups.

Glossary

Chronosequence A series of sites that differ in age, but otherwise occur on similar soil types and environmental conditions within the same climatic zone.

Forest regeneration The process of forest regrowth on land that was formerly forested.

Old-growth forest A forest undergoing a late stage of succession that is relatively stable with regard to forest structure, ecosystem function, and species composition.

Primary succession The development of an ecosystem on a substrate previously devoid of vegetation.

Secondary succession The re-establishment of an ecosystem following a disturbance that removes existing vegetation.

Shifting cultivation A cyclic agricultural system widely used throughout the tropics involving cutting and burning of small patches of forest, followed by several years of crop cultivation, followed by a fallow period, during which forest regenerates and can be cleared again.

Introduction: Deforestation and Forest Regeneration in the Tropics

The twentieth century was a period of unprecedented deforestation in the world's tropical regions. There are hopeful signs that these rates are slowly declining due to increasing rates of reforestation (replanting) and natural forest regeneration. The rates of tropical deforestation declined from 16 million ha yr⁻¹ during the 1990s to 13 million ha yr⁻¹ from 2000 to 2010 (FAO, 2010). In Africa and Asia, less than 20% of the forests in 2010 were classified as primary (old-growth) forests, with no visible indications of human disturbance. Some tropical countries, such as Vietnam, Costa Rica, El Salvador, Puerto Rico, and India, have shown a net gain of forest cover over the past 10–20 years (Chazdon, 2008a). Although forest regeneration in the tropics cannot replace lost old-growth forests, regrowth forests offer suitable habitats for many forest-requiring species (Chazdon *et al.*, 2009b; Dent and Wright, 2009) and represent major sinks for atmospheric carbon, partially offsetting global carbon emissions (Pan *et al.*, 2011). Moreover, regenerating tropical forests provide essential sources of timber and nontimber products that support millions of forest-dependent people.

The small spatial scale of land-use change and the difficulty of distinguishing early stages of secondary growth from plantations or short-term fallows create significant challenges for assessing the area of tropical forests undergoing natural regeneration. Asner *et al.* (2009) classified at least 1.2% of the humid tropical forests around the world as forests undergoing long-term secondary regeneration at the end of the twentieth century. This highly conservative estimate does not include forests committed to regeneration before the 1990s and is based on selected areas with time series of satellite-based data. The increased prominence of tropical regrowth forests around the world signals an urgent need to understand the underlying biophysical and social factors that influence their regeneration following agricultural abandonment and natural disturbance.

Tropical forests undergo periods of disturbance and recovery at different spatial and temporal scales (Chazdon, 2003). Natural disturbances, such as hurricanes, floods, and fires, completely or partially remove forest cover and alter

soils, with dramatic consequences for biodiversity and ecosystem functions (Whitmore and Burslem, 1988). Forest clearing for cultivation, establishment of pastures, or harvesting timber creates intensive and extensive disturbances. In the aftermath of large-scale disturbances, successional processes bring about changes in the species that form forest communities, species population sizes and structure, species interactions, and ecosystem properties. Successional pathways and rates of change vary widely according to the nature of prior land use, the proximity of old-growth forest, and the availability of fauna (Chazdon *et al.*, 2007).

Forest regeneration is a community- and ecosystem-level process of secondary succession on cleared land that was formerly forested. The successional process follows a progression of stages during which forest assemblages gradually become enriched with species and increase in structural and functional complexity. Old fields that replaced abandoned clearings, pastures, or cultivated fields, turn into young, regenerating forests dominated by fast-growing, highly dispersed pioneer tree species. Over the time, plant and animal species characteristic of nearby old-growth forests gradually replace successional pioneer species. Depending on the longevity of early-colonizing tree species, old-growth forests can re-establish within 100–200 years (Wirth *et al.*, 2009). But succession can become arrested or deflected following intensive and large-scale land uses that deplete soil fertility or reduce the availability of local biota. In these cases, restoration interventions are needed to assist in the establishment of native tree species.

Tropical Forest Succession Following Natural and Human Disturbances

Historical Legacies of Tropical Forest Disturbance

Today's tropical forests represent the legacy of successive waves of colonization, exploitation, cultivation, abandonment, and regrowth, shaped by human occupations, cultural change, natural disasters, and climate change. Hurricanes and fires also occurred repeatedly during prehistory, influencing the

composition and regeneration of tropical forests. Following a prehistoric hurricane at Laguna Negra in southern Nicaragua between 3830 and 2820 years ago, a series of fires occurred over approximately 200 years, followed by repeated cycles of forest regeneration and burning by fires over several thousand years (Urquhart, 2009). Volcanic eruptions destroyed former forests and gave rise to new ones in New Guinea, Sumatra, and Krakatoa. In Amazonian Ecuador, a catastrophic flood wiped out an entire forest area and its human inhabitants more than 500 years ago. The forest has been regrowing since then, but species composition remains distinct from nearby forests that were spared in the historic flood (Pitman *et al.*, 2005).

The legacies of ancient occupations by hunter-gatherers and later periods of extensive and intensive landscape transformation by agricultural societies are still evident in today's tropical forests. Early hunter-gatherers significantly altered forest cover, led to the geographic spread of key food plants, and contributed to the extinction of some of the Pleistocene megafauna. Forest dwellers practiced early cultivation of forest tubers and arboriculture of fruit trees, increasing the concentration, abundance, and geographic ranges of plant species used for food and shelter in their camps, settlements, and rock shelters. Late Pleistocene colonists in the New Guinea Highlands fashioned stone tools to clear trees, enhancing the supply of *Pandanus* seeds, an important staple food (Summerhayes *et al.*, 2010). These early occupations are associated with increasing frequency of fire and changes in hydrology. In the Neotropics, Paleoindians hunted, fished, and gathered fruits along rich alluvial floodplains and bluffs of major rivers and along coastlines. Human populations extended into upland areas, where they engaged in broad-spectrum hunting and collecting in areas away from streams and practiced small-scale gardening.

Indigenous peoples of Mesoamerica cultivated trees and managed forest patches for more than 3000 years. The Maya planted homegardens and managed forest fallows and older forests. Forest gardens were so widespread during the Mayan Preclassic period that contemporary forests of the southeastern Peten, eastern Guatemala, and western Belize are considered to be anthropogenic in origin (Campbell *et al.*, 2006). Aggregations of useful tree species in forests surrounding archeological sites today provide strong evidence of silvicultural management by ancient peoples (Ross, 2011). The persistence and management of tree cover in Mayan landscapes likely favored the rapid regeneration of forest following the Maya collapse several hundred years later after the Spanish Conquest. In the Mirador Basin of the northern Peten region of Guatemala, sediments of Lago Puerto Arturo reveal a history of forest clearing beginning more than 4000 years ago, followed by 2000 years of agricultural activity, and sudden abandonment around AD 1000, at the end of the Late Classic Period (Wahl *et al.*, 2006). Legacies of ancient arboriculture systems are still evident in the current vegetation of the Solomon Islands and throughout Melanesia and Oceania.

The development and spread of agriculture profoundly impacted the structure and composition of tropical forests. Human activity over more than hundreds to several thousand years also produced changes in soil properties and landscape hydrology across the Brazilian Amazon basin and in regions of Columbia, Ecuador, Peru, Venezuela, Bolivia, the Guianas,

and West Africa (Woods, 2009). In the depths of the Darien forests of Panama, pollen cores document nearly 4000 years of land clearing and maize cultivation (Bush and Colinvaux, 1994). These areas were abandoned abruptly about 320 years ago, shortly after the Spanish conquest, and have not been resettled. The forests surrounding these areas are now in a late stage of secondary succession. As canopy trees often live greater than 300 years, these forests – and many other so-called “primary” forests in Mesoamerica – are still undergoing gradual successional changes in composition and stand structure, as current canopy trees may represent only the second generation of trees since this forest began to regenerate (Bush and Colinvaux, 1994).

Forest Dynamics and the Successional Continuum

Nonequilibrium theories have displaced equilibrium views, shedding new light on the nature of successional change and responses to disturbance. There is no particular moment when a forest reaches a stable or a “climax” state, as disturbances frequently occur, even during late stages of succession (Chazdon, 2008b). Characterization of species as “early-successional” versus “late-successional” often involves arbitrary distinctions based on the nature of the forests where different species colonize, recruit, and reproduce. Replicated landscape-level surveys of species abundance in second-growth and old-growth forests can be used to classify species according to their specialization in different forest types using rigorous statistical approaches.

Forest successional stages can be defined based on three major criteria: total aboveground biomass, age, or size structure of tree populations, and species composition. These characteristics change at different rates and vary differentially with the spatial scale of measurement. Multiple successional pathways can be observed within a particular tropical region, often reflecting differences in prior land use (Mesquita *et al.*, 2001). Most methods used to detect forest disturbance or change are based on measures of forest structure, such as basal area, which tend to approach stability more quickly than measures of species composition (Letcher and Chazdon, 2009). The only way to distinguish old secondary forests from forests that have not been disturbed by humans or catastrophic forces of nature is through detailed knowledge of species growth and regeneration patterns and careful studies of past stand history.

Successional processes occur in all forests at different spatial and temporal scales. The term “old-growth forest” describes forests at a late stage of succession that are relatively stable with regard to these criteria. Forest dynamics do not stop when a forest has reached a late stage of succession, but they shift toward localized (endogenous) disturbances such as tree-falls or local flooding that do not uniformly characterize the entire forest assemblage.

Successional Trajectories and Stages

Successional trajectories are influenced by the scale, frequency, and intensity of previous disturbance or land use, by soil

texture and nutrient availability, by the nature of remnant vegetation, and by conditions following disturbance, including types of management, colonization of invasive species, and dispersal of seeds from surrounding forest areas (Chazdon, 2003, 2008b). Mesquita *et al.* (2001) describe two distinct successional pathways on abandoned agricultural land in Central Amazonia. In sites where the period of intensive land use was more than 4 years and fire was used during the initial clearance of forest, species of *Vismia* dominate early stages of succession. In contrast, *Cecropia* species dominate in areas where pastures were used for less than 2 years in both burned and unburned sites. Floristic turnover in *Cecropia* stands showed strong and consistent negative frequency dependence, whereas *Vismia* stands exhibited little or no frequency dependence (Norden *et al.*, 2011). Patterns of early species colonization and dominance following land abandonment strongly affect successional changes in vegetation structure and composition (Chazdon, 2008b).

Dividing successional pathways into distinct stages or phases is a useful approach that enables comparative studies and examination of ecological processes that affect transitions in the forest structure, composition, and ecosystem properties (Chazdon, 2008b, Table 1). The boundaries between successive successional stages are fuzzy, but the temporal sequence of these stages generally follows consistent patterns. Table 1 illustrates the vegetation dynamics processes that occur during successive stages of tropical forest succession. During the stand initiation stage, pioneer trees colonize and

establish, herbaceous vegetation declines, and shade-tolerant tree species begin to establish as seedlings. Canopy closure ushers in the stem exclusion stage, when shade-intolerant species of trees, lianas, and shrubs below the canopy become suppressed and die, whereas shade-tolerant species recruit in the subcanopy and canopy and continue to establish as seedlings. During the long understory-reinitiating stage, long-lived pioneer trees in the canopy begin to die, forming canopy gaps, which increase heterogeneity in light availability. This stage is associated with turnover of species in the canopy, whereas the earlier stem exclusion stage is associated with turnover of species in the understory. The old-growth stage begins with the mortality of the last remaining pioneer trees that established during the stem initiation stage (Wirth *et al.*, 2009). This stage is the most diverse for trees and epiphytes and is characterized by high spatial heterogeneity and high functional diversity (Table 1).

Chronosequences versus Dynamics

Our current understanding of secondary forest succession in the tropics emerges primarily from chronosequence studies (Brown and Lugo, 1990). A chronosequence is a series of sites that differ in age since abandonment or disturbance, but otherwise occur on similar soil types and environmental conditions within the same climatic zone under the same historic land use. Sites are replicated in space as a substitute for replication in time. Chronosequence studies rely on the

Table 1 Vegetation dynamics processes associated with stages of secondary succession and time since disturbance in tropical forests

<i>Time since disturbance/successional stage</i>			
<i>0–15 years</i> <i>Stand initiation</i>	<i>15–50 years</i> <i>Stem exclusion</i>	<i>30–200 years</i> <i>Understory reinitiation</i>	<i>> 200 years</i> <i>Old-growth</i>
Germination of seeds in seed-bank	Canopy closure	Mortality of canopy trees	Mortality of pioneer cohort in canopy
Resprouting of remnant trees	High mortality of lianas and shrubs	Formation of small canopy gaps	Range of gap sizes
Colonization of short- and long-lived pioneer trees	Recruitment of shade-tolerant seedlings, saplings, and trees	Canopy recruitment and reproductive maturity of early-colonizing species	Recruitment of shade-tolerant and gap-requiring canopy species and emergents
Rapid height and diameter growth of woody species	Growth suppression of shade-intolerant trees in understory and subcanopy	Increased heterogeneity in understory light availability	Spatial heterogeneity in biomass and microtopography
High mortality of herbaceous species	High mortality of short-lived, pioneer trees	Seedling and sapling establishment of shade-tolerant tree species	Large woody debris
High rates of seed predation	Dominance of long-lived pioneer trees	Tree recruitment of early-establishing shade-tolerant species	Maximum diversification of trees and epiphytes
Seedling establishment of shade-tolerant tree species	Development of canopy and understory tree strata		
	Seedling establishment of shade-tolerant tree species		

Successional stages are based on the framework Oliver and Larson (1990). Actual time ranges vary widely among tropical forest regions and land uses.

critical assumption that fields abandoned at different times in the past experienced the same changes, processes, and conditions during their formation. This space-for-time substitution allows the study of a wide range of successional stages and makes it possible to sample considerably more sites than could be accommodated through site-intensive long-term studies. Chronosequence approaches are used to study primary succession in the tropics following landslides, volcanic eruptions, and river channel flooding.

Chronosequence studies require detailed knowledge of land-use history and time since disturbance or since abandonment of each stand. In seasonal tropical forests, trees with annual growth rings can often be used to date forest age or past fire events. Few tropical forest chronosequences include sites more than 80–100 years old. Well-replicated samples from different forest patches within each forest age class are needed for robust chronosequence studies. Ideally, study sites should be selected without systematic bias in forest attributes or land-use history, but this is not always feasible. Increasing intensification of land-use and landscape change in the tropics over the past 150 years creates challenges for chronosequence studies.

Long-term studies of vegetation dynamics in successional forests often reveal idiosyncratic patterns in individual sites driven by initial species composition, site factors, land-use history, and landscape composition. With few exceptions, these patterns are not consistent with chronosequence predictions. Chronosequence data for basal area, stem density, and species density of trees > 10 cm diameter were compared with time-series data over 9 years on vegetation dynamics in eight successional stands in northeastern Costa Rica (Chazdon *et al.*, 2007). Only basal area showed a consistent trend between the chronosequence and the time series. A similar analysis compared chronosequence data with 3-year time series data for 10 successional sites in Chiapas, Mexico, regenerating on shifting cultivation fallows (van Breugel *et al.*, 2006). In this case, fallow age was not a significant predictor of either plot basal area or stem density across the chronosequence (Chazdon *et al.*, 2007). Feldpausch *et al.* (2007) tested chronosequence predictions of secondary forest growth and biomass accumulation with 4 years of time-series data in 10 secondary forests growing on abandoned pastures in Central Amazonia. The youngest forests consistently accumulated less biomass per year than the predicted trend due to a low initial density of trees following a longer duration in pasture (Feldpausch *et al.*, 2007).

When sites within a chronosequence share similar land-use history, environments, and species pools, patterns of successional change are more consistent within and across plots of different age since abandonment. In tropical dry forest of Oaxaca, Mexico Lebríja-Trejos *et al.* (2010) observed successional changes over 4 years within 16 plots ranging from 1 to 60 years old that generally matched chronosequence trends, particularly when pioneer and nonpioneer species were considered separately. Chronosequences and long-term, plot-based studies should be viewed as complementary approaches to the study of successional rates and processes. Besides the difficulty in matching land-use history and environmental conditions across sites, chronosequence studies do not provide direct information on successional processes or

vegetation dynamics. The only way to quantify these processes is to monitor changes in forest structure, composition, and function overtime within sites of known disturbance history and landscape surroundings.

Sources of Regeneration

Following abandonment of cultivated fields or pastures or after a forest-clearing disturbance, new vegetation recruits arise from five major sources: the soil seed bank, newly dispersed seed, resprouting damaged stems, and advance regeneration – the local pool of existing seedlings and saplings that survived the disturbance. Many mature forest species are capable of resprouting from roots or stems after forest clearing and burning (Kammesheidt, 1999). The vigorous growth of sprouts confers a competitive advantage during the early stages of forest succession. In abandoned shifting cultivation fallows in Eastern Amazonia, 81–86% of the individuals and 68–81% of trees originated from sprouts (Vieira and Proctor, 2007). The density of resprouts in shifting cultivation fallows in a tropical moist forest region of Paraguay declined with fallow age (Kammesheidt, 1999). Resprouting is also an important mechanism for tree regeneration following logging and cyclones. As land-use intensity increases, as in frequent burning, weeding, and bulldozing of pastures, sprouting is no longer a source of new recruits following abandonment. Resprouting is a particularly important mechanism of recruitment in tropical dry forests, where the rates of seedling establishment may be reduced by desiccation and plant species are adapted to aboveground dieback during droughts.

In large abandoned pastures and swidden fallows, the main seed sources for initial colonization during secondary succession come from either the soil seed bank or newly dispersed seed. Many pioneer trees with small seeds in the seed bank require direct exposures of red light for germination (Vazquez-Yanes and Orozco-Segovia, 1993). In abandoned pastures of Chiapas, Mexico, the seed bank was more important than the seed rain for the recruitment of early-successional tree species, but the opposite was true for late-successional species (Benitez-Malvido *et al.*, 2001). In most cases, seeds of late-successional species are rarely found within the soil seed bank (Vazquez-Yanes and Orozco-Segovia, 1993).

The soil seed bank is severely depleted in tree and shrub species following many years of grazing and burning to establish and maintain pasture or plant crops, placing an even greater reliance on the arrival of seeds transported by wind or delivered by frugivorous vertebrates. The rate of new seed dispersal decreases with clearing size and distance from forest edge, retarding the initiation of secondary succession in large clearings (Cubina and Aide, 2001). However, if birds and bats are attracted to perching sites on fruiting shrubs or trees within pastures or fallows, the rate of succession accelerates through increased quantity and diversity of seed dispersal and enhanced recruitment of woody species, including species characteristic of mature forests. Seedling establishment of vertebrate-dispersed species during initial stages of succession is enhanced beneath remnant trees compared with areas away from remnants within the same site (Guevara *et al.*, 1986).

Besides their role in nucleating succession, remnant trees can facilitate forest regeneration in at least three other ways. First, isolated trees serve as sources of seed for tree regeneration beneath other isolated remnant trees and as pollen and seed sources for regenerating trees in forest fragments and secondary forests. Second, isolated pasture trees store seed of forest tree species in canopy soil that accumulates within their crowns (Nadkarni and Haber, 2009). Third, isolated remnant trees in pastures continue to influence tree recruitment beneath their crowns beyond the initial stages of succession, even after canopy closure (Schlawin and Zahawi, 2008).

Effects of Prior Land Use and Soil Fertility

The intensity, extent, severity, and duration of land use have direct consequences on sources of regeneration, soil nutrient availability, and conditions for early seedling establishment, including competition with crop species and weeds. When initial stand disturbances are small, land use is of a short duration, and clearings are embedded in a forest matrix, tree species and biomass accumulate rapidly. Intensive land use, short fallow times, and frequent burning reduce soil nutrient availability, increase soil compaction, reduce soil water-holding capacity, and restrict seed availability and seedling establishment. Exotic pasture grasses can also negatively affect the establishment of woody plants. During repeated cycles of shifting cultivation in Kalimantan, Indonesia, the species diversity of both early- and late-successional species declined with increasing numbers of cycles, due to changes in the surrounding landscape that affected local species availability (Lawrence, 2004).

Secondary succession generally proceeds more rapidly on young, fertile, volcanic soils, compared with weathered, nutrient-poor soils (Guariguata and Ostertag 2001). In shifting cultivation fallows of white-sand vegetation in the Venezuelan Amazon, saplings of mature forest tree species took 60 years to become more abundant than early-successional species (Saldarriaga *et al.*, 1988). In contrast, sapling assemblages in 15–20-year-old secondary forests on abandoned pastures on volcanic soils in northeastern Costa Rica were already becoming dominated by mature forest species (Norden *et al.*, 2009). Across five regions of the Amazon Basin, the rates of forest regrowth, as measured by stand height, were the highest in the Altamira region, which had the highest soil fertility (Moran *et al.*, 2000). In the Bragantina region of Brazil, 150 years of land clearance for agriculture has led to slow and impoverished forest regrowth due to low seed availability and poor soil quality (Tucker *et al.*, 1998).

Successional forests across five regions of the Amazon basin showed faster rates of height growth in shifting cultivation fallows than in either abandoned pastures or in fields used for mechanized agriculture, and shifting cultivation fallows generally had higher rates of aboveground biomass accumulation than more intensive land uses (Moran *et al.*, 2000). Expanding this study to nine locations, Zarin *et al.* (2005) found that the rates of biomass accumulation in secondary forests stands across the Amazon basin were strongly affected by the number of previous burns, which often serves as a proxy for the number of shifting cultivation cycles. On average, stands with five or more previous burns showed a

reduction in biomass accumulation of more than 50% compared with stands that burned only once or twice (Zarin *et al.*, 2005). Repeated cycles of shifting cultivation can also reduce the levels of available soil nutrients during fallow periods. After three cultivation–fallow cycles in tropical dry forests of the Yucatan Peninsula in Mexico, the levels of available phosphorus declined by 44%, creating a negative feedback cycle of increasing phosphorus limitation in regenerating vegetation (Lawrence *et al.*, 2007).

Recovery of Ecosystem Processes

When a tropical forest is cleared, burned, cultivated, or grazed, a substantial fraction of the living biomass is lost from the ecosystem. The fate of carbon and nutrients in the soil following forest clearing varies widely depending on the type and the intensity of land use, as well as soil texture and clay content. In a humid tropical region of Mexico, conversion of forests to pastures or cornfields led to the loss of 95% of the aboveground pool of carbon, 91% of the aboveground pool of nitrogen, and 83% of the aboveground pool of phosphorous (Hughes *et al.*, 2000). As pastures are generally not tilled or cultivated, little or no carbon is lost in the top 100 cm of soil. Conversion of forest to active pasture in northeastern Costa Rica did not lead to significant loss of soil carbon (Powers, 2004). Conversion of tropical old-growth forests to cropland resulted in a 25% loss of soil organic carbon, twice as much as when old-growth forests are converted to pasture (Don *et al.*, 2011).

The losses of carbon and nutrients following forest clearing and burning are gradually reversed during forest regeneration. Lost soil organic matter is restored due to the decomposition of litterfall and root biomass production. Regenerating forests rapidly accumulate nutrients in vegetation, litter, and soil, particularly during the first 20 years (Brown and Lugo, 1990). The rapid development of leaf biomass contributes to litterfall and to the rapid accumulation of total biomass during the stand initiation stage (Table 1). Woody biomass (stems and roots) accumulates over a longer time frame, as trees continue to grow in height and diameter over several decades (Brown and Lugo, 1990).

Approximately 45–50% of this biomass is composed of carbon. During the first 20 years of succession, the rates of aboveground carbon accumulation are generally higher in moist and humid forests than in dry forests, and on former agricultural land than former pastures (Marin-Spiotta *et al.*, 2008). Regenerating forests in the tropics are major sinks for carbon; the global carbon sink formed by tropical regrowth forests was estimated to reach 1.7 ± 0.5 PgC years from 2000 to 2007, greater than the carbon sink from intact tropical forests (Pan *et al.*, 2011).

Chronosequence studies have been widely used to estimate the rate of accumulation of carbon and nutrients in above- and belowground stocks during secondary forest regeneration. Based on a chronosequence study in the Venezuelan Amazon, Saldarriaga *et al.* (1988) estimated that forests regrowing following shifting cultivation require 190 years to reach levels of aboveground biomass observed in old-growth forests. In tropical dry forests of the Yucatan Peninsula in Mexico, aboveground biomass was estimated to reach old-growth forest levels within 65–120 years of succession (Read and

Lawrence, 2003). Chronosequence studies in humid Neotropical forests have found higher levels of aboveground biomass in older secondary forests than in old-growth forests (Letcher and Chazdon, 2009). In these cases, the higher aboveground biomass in older secondary forests could be due to the lower biomass of subcanopy and canopy palms, which are more abundant in old-growth forests. In contrast to aboveground carbon stocks, soil carbon stocks do not change appreciably over time during forest regeneration on former pastures (Marin-Spiotta *et al.*, 2009). Aboveground pools of nitrogen, phosphorus, and sulfur increased with age during forest regeneration in humid forests of Los Tuxtlas in Mexico (Hughes *et al.*, 1999) and in Central Amazonia (Feldpausch *et al.*, 2004). Fixation of nitrogen by legumes during early succession allows the rapid recovery of nitrogen levels in shifting cultivation fallows in Amazonia (Gehring *et al.*, 2005).

Biodiversity and Tropical Forest Regeneration

Functional Diversity of Vegetation

Tropical forest regeneration follows a general theme of replacement of shade-intolerant, fast-growing species with shade-tolerant, slower-growing species. These changes bring about transitions in the dominance of different plant growth forms and functional types. Grasses, herbs, vines, and shrubs dominate recently abandoned fields, but decline in abundance as the forest canopy closes and reduces light availability (Chazdon, 2008b). Much of this replacement takes place during the stand initiation and stem exclusion stages beneath the developing canopy of long-lived pioneer trees, which themselves become replaced by both shade-tolerant and gap-requiring tree species only during later stages of succession. Pioneer and shade-tolerant species in tropical forests exhibit contrasting values of many leaf, wood, and seed traits that are important determinants of plant growth and survival (Bazzaz and Pickett, 1980). Poorter *et al.* (2004) ranked 15 tree species from lowland moist forest in Bolivia according to their successional position, based on abundance patterns during succession following shifting cultivation. Six leaf traits showed significant linear relationships with species successional position. Specific leaf area, leaf water content, leaf nitrogen content, and leaf phosphorus content all declined from the early- to the late-successional position, whereas the leaf carbon : nitrogen ratio and lignin content increased. Leaf lifespan also increased in a linear manner from early- to late-successional position, whereas herbivory rates declined (Poorter *et al.*, 2004). Wood density of plant stems and branches also shows successional trends; fast-growing species that dominate early in succession generally have low wood density, whereas slow-growing species that dominate later in succession generally have high wood density (Poorter, 2008).

Changes in Species Composition

Tropical old-growth forests are among the most species-rich terrestrial assemblages on earth. How species composition changes over long time scales during succession remains poorly understood, as few studies have followed such changes

for more than a few years. Compositional changes are driven by complex interactions among local site factors, past site history, and by dynamic landscape and regional factors. The structural, functional, and taxonomic diversity of vegetation increases during succession. The analysis of successional trends in species composition is a challenging prospect for at least five reasons. First, almost all of our knowledge on changes in species composition during succession is based on short-term studies (less than 50 years in duration) or on chronosequence studies. Comparisons of species richness or diversity across a chronosequence are insufficient to assess similarity of assemblages, due to the high rates of species turnover during succession and site-specific trajectories of species composition (Chazdon *et al.*, 2007). Second, assessments of the long-term recovery of a particular species during succession assume that no changes in species composition or population abundance have occurred over this same time interval in old-growth areas that serve as reference points. Third, the classification of old-growth specialists in a particular region or landscape is rarely based on robust statistical procedures and is highly subjective. Fourth, in many regions, old-growth forests used as reference points and for classifying specialists do not occur within the same elevational zone or soil type as second-growth forests, owing to the landscape variation in deforestation and land abandonment. Thus, spatial differences in composition may be confounded with successional changes. Fifth, secondary forests are often cleared before there is an opportunity to assess long-term successional trajectories and species gain in these forests (Chazdon *et al.*, 2009b).

In humid forest regions, woody species composition recovers slowly but steadily in abandoned pastures and shifting cultivation fallows (Guariguata and Ostertag, 2001; Chazdon, 2008b). In the Southern Atlantic Forest region of Brazil, only 3.1% of the original forest cover remains. Piotto *et al.* (2009) inventoried trees > 5 cm DBH (diameter at breast height) in 12 secondary forests in three age classes (10, 25, and 40 years) following shifting cultivation of manioc. The similarity of species composition between second-growth forests and old-growth forests in the region increased with stand age, due to the gradual establishment of old-growth tree species (Piotto *et al.*, 2009). The proportion of trees classified as pioneer species declined steadily with forest age class, and more than half of the species found in 40-year-old stands were shared with neighboring old-growth forests. The percent of known local endemics and Atlantic forest endemics also increased with age across these stands, whereas widespread species decreased.

Across a chronosequence in tropical rain forests of lowland NE Costa Rica, species composition and species richness of stems > 2.5 cm DBH did not differ significantly between older regenerating forests (30–42 years old) and old-growth forests (Letcher and Chazdon, 2009). The proportion of old-growth species present in second-growth forests increased significantly with age since abandonment (Figure 1), suggesting that the establishment of old-growth species increases steadily with time during at least the first 50 years of succession in this region. In seedling assemblages of 15–25-year-old regenerating forests, the proportion of old-growth species increased to 59–75%, reflecting conditions favorable for seedling recruitment (Norden *et al.*, 2009).

Figure 1 The proportion of old-growth woody species occurring in secondary forest assemblages increases significantly with time since pasture abandonment in regenerating lowland rain forests of northeastern Costa Rica (Letcher and Chazdon (2009); $R^2=0.79$; $P<.001$). Data are based on 0.10 ha vegetation samples of stems >2.5 cm DBH in 21 secondary forest stands.

Few studies have assessed the long-term recovery of tree species composition and endemism of trees during secondary succession. Regenerating forests on former coffee plantations in the Blue and Port Royal Mountains of Jamaica did not differ significantly from adjacent old-growth forests in basal area, the overall number of species, or the number of endemic species (Chai and Tanner, 2011). Endemic species were less abundant in the second-growth forests, however, despite 150 years of succession. More than half (54%) of the species present in nearby old-growth forest were present in the regrowing plantations, suggesting that old-growth tree species are gradually establishing in these forests (Chai and Tanner, 2011).

Recovery of animal populations and species composition during succession depends heavily on recovery of vegetation (Chazdon *et al.*, 2009b). Regenerating forests provide different types and amounts of resources (food and shelter) for animals at different stages. Based on a review of 10 studies, Karthik *et al.* (2010) reported that 70% of old-growth forest birds had returned within 25 years of abandonment of shifting cultivation fields. Bird species diversity and composition in 14–19-year-old second-growth forests of Jari, Brazil, are distinct from surrounding old-growth forests however, suggesting that many years are needed for establishment of old-growth specialist bird species (Barlow *et al.*, 2007b). Second-growth forests supported a higher abundance of ungulate browsers and small-bodied primates than old-growth forests but lower abundance of large-bodied birds and large primates (Parry *et al.*, 2007). Studies of 15 taxonomic groups in this region showed idiosyncratic responses to land-use change; 95% of old-growth orchid bee species occur in second-growth, but less than 40% of old-growth tree and liana genera were found in second growth (Barlow *et al.*, 2007a). Volant invertebrates and vertebrates (butterflies, birds, and bats) generally show faster rates of influx into regenerating forests than do nonvolant animals (Chazdon *et al.*, 2009b). Of the 30 species of non-volant mammals detected in old-growth forests in the humid forest region of Los Tuxtlas, Mexico, only 11 were detected in 25–35-year-old forests and eight in 5–15-year-old forests (Estrada *et al.*, 1994).

Dent and Wright (2009) examined 65 studies that compared faunal diversity (birds, reptiles, amphibians, invertebrates, and mammals) in tropical old-growth and forests regenerating following complete clearance. Of the 114 regenerating sites, only 11 were more than 40 years old. On an average, the mean proportion of old-growth animal species present in regenerating forests was 58%. More than 50% of species present in regenerating forests less than 10 years old were also present in old-growth. Moreover, the composition similarity (presence-absence-based Sørensen Index) between old-growth and young regenerating forests was similar to levels of similarity evaluated exclusively among old-growth sites (Dent and Wright, 2009). Among the 22 studies that included regenerating forests of different ages, faunal similarity between regenerating and old-growth forest increased significantly with increasing time since abandonment. This increase in similarity is due to an increasing percent of old-growth animal species that are present in regenerating forests over time, reaching 80% in forests older than 50 years (Dent and Wright, 2009). Species composition of animal communities in forests regenerating following intensive agriculture or pasture was less similar to animal communities in old-growth forests than those recovering from shifting cultivation or that were cleared without cultivation. Regenerating forest adjacent to old-growth forests had higher levels of faunal similarity to old-growth forest than forests that were not adjacent (Dent and Wright, 2009).

It is important to recognize that regenerating tropical forests cannot support all species that lived in local forests before they were cleared (Dent and Wright, 2009). Species with highly specialized dietary or habitat requirements are often missing from regenerating forests. Large-bodied canopy frugivores and understory insectivores are adversely affected by habitat disturbance and are often restricted to old-growth forests (Karthik *et al.*, 2010). Furthermore, patches of regenerating forests are often small, isolated, and close to roads, further reducing their occupancy by rare species and species that cannot cross unforested habitat (Lees and Peres, 2009). Hunting pressures are also very high in regenerating forests, because they are often close to agricultural fields and human communities (Karthik *et al.*, 2010).

Seed Dispersal and Predation

The lack of seed dispersal to abandoned areas can be a major obstacle to forest regrowth. For 50–90% of the tree and shrub species in tropical forests, dispersal is assisted by animals (Howe and Smallwood, 1982). But most frugivorous animals will not venture into abandoned areas unless they encounter suitable resources for feeding or perching. Open conditions in clearings expose frugivores to increased predation risk and offer a lower availability of fleshy fruits. These factors lead to a steep decline in seed rain with increasing distance from the forest edge (Duncan and Chapman, 2002). Isolated remnant trees, shrubs, and pioneer trees in abandoned pastures and cultivated fields attract frugivores, leading to higher densities of seed deposition and recruited seedlings (Laborde *et al.*, 2008).

Bats and birds are the major biotic dispersal agents for early-successional trees and shrubs in the tropics. In humid

forest areas of Chiapas and Mexico, bats dispersed more seeds than birds did in early-successional habitats (Medellin and Gaona, 1999). Birds tend to deposit seeds beneath fruiting trees or carry fruit to perches or nests, where they drop or defecate seeds (Corlett, 1998). Although bats also deposit seeds below fruiting trees, they also defecate small seeds during flight. Bat-dispersed seeds are therefore more likely to reach abandoned areas that lack perching or nesting sites than bird-dispersed seeds. Phyllostomid bats play a particularly important role in seed dispersal during both primary and secondary succession (Muscarella and Fleming, 2007). Species that often dominate early stages of succession in the Neotropics are concentrated in four of the five top plant families that frugivorous bats consume (Solanaceae, Moraceae, Piperaceae, and Clusiaceae; (Muscarella and Fleming, 2007). With the exception of Moraceae (*Ficus* and *Musanga* species), bat-dispersed plants rarely dominate early stages of succession in the Old World. Early-successional fleshy fruits in the tropical Africa and Asia are dispersed primarily by birds (Gonzales *et al.*, 2009).

Animal-mediated seed dispersal is poorly studied beyond the stand initiation stage. Early-successional forests are dominated by small-seeded species, whereas large-seeded species increase in importance during later successional stages (Westoby *et al.*, 2002). Frugivore body size is the major determinant of the ability to feed on fruit of a given size. Thus, large seeds (and the large fruits that contain them) are generally dispersed by large-bodied frugivores. One exception to this trend is the dispersal of large seeds (>8 mm diameter) by small-bodied tent-roosting bats, such as *Artibeus watsonii* in humid Neotropical forests (Melo *et al.*, 2009). Seed deposition beneath leaf tent roosts of this species significantly increased the species richness and abundance of large-seeded species in regenerating forests of northeastern Costa Rica (Melo *et al.*, 2009). Small-bodied primates can also be important dispersers of large seeds in secondary forests. Mixed-species groups of tamarins (*Saguinus mystax* and *Saguinus fuscicollis*) dispersed 63 tree species with seeds >1 cm diameter in a 9-year-old regenerating forest adjacent to old-growth forest in northeastern Peru (Culot *et al.*, 2010).

The spatial distribution of vertebrate-dispersed seedlings, saplings, and trees in regenerating forests may reflect a long-term legacy of remnant trees and their interactions with frugivorous vertebrates. In montane forests of Costa Rica, remnant trees influenced the composition of regeneration 3 and 14 years after abandonment; late-successional species were more abundant than early-successional species only beneath remnant trees. In the Caribbean lowlands of Costa Rica, tree and sapling density decreased with increasing distance from remnant trees 23 years after pasture abandonment (Schlawin and Zahawi, 2008). Remnant trees also influenced the species composition of recruited trees, favoring the establishment of species with seeds >1 cm diameter.

Dispersal agents vary in their importance during the early, middle, and late stages of forest regeneration (Table 1). Initially, if no remnant vegetation is present, wind and bats play particularly important roles in the dispersal of small-seeded species. Once perches become available, frugivorous birds become frequent visitors and increase the taxonomic diversity, size, and functional diversity of seeds arriving at regenerating

forests. As regenerating vegetation becomes more developed and diverse, increasing availability of resources for roosting and feeding encourages a wide diversity of small- and large-bodied vertebrates to become regular visitors and residents in regenerating forests, carrying with them the fruits and seeds of old-growth species from the surrounding areas. The progression of vegetation during regeneration facilitates colonization of new species. During mid- and late-successional stages, the only barriers to seed dispersal are distance from seed sources of rare or infrequently fruiting trees, availability of dispersal agents, and time. Even after 100 years of regeneration, forests in the central catchment reserve of Singapore were depleted of many tree species above 30 cm DBH found in contiguous old-growth forests in the region (Turner *et al.*, 1997). Large-seeded old-growth tree species likely require large-bodied frugivores to disperse their seeds, but these species are now extinct or extremely rare in Singapore (Corlett, 1992).

Following dispersal, seeds are subject to attack by vertebrates, invertebrates, and fungi. The rates of seed predation are high in pastures, often exceeding 50% (Scariot *et al.*, 2008). Small seeds (<0.2 g) dispersed into pastures are consumed by ants and other insects, whereas medium-sized seeds (0.2–4.0 g) are often consumed by rodents (Myer, 2008). In regenerating forests, mammals appear to be more important seed predators than insects for large-seeded species such as palms. The rates of seed predation were higher in shifting agriculture fallows than in mature forest gaps (Uhl, 1987), and the removal rate of seeds declined with age since abandonment (Pena-Claros and de Boo, 2002).

Declines in vertebrate abundance due to hunting can decrease the levels of seed predation, leading to changes in the species composition of regenerating vegetation. Although these effects are poorly studied in successional forests, declines in populations of mammalian seed predators may lead to increased recruitment of large-seeded species or species that are less susceptible to insect predation (Stoner *et al.*, 2007).

Conclusions: The Broader Context of Tropical Forest Regeneration

Most regenerating forests in the tropics are found in relatively small patches within a matrix of old-growth forests, logged forests, and agricultural fields or pastures. Regeneration pathways and rates of change strongly depend on the surrounding landscape conditions, which are often highly dynamic. Moreover, landscape conditions are often related to the duration and intensity of prior land use that influence regeneration at a local level. Ultimately, forest regeneration is part of a broader socio-ecological system that governs patterns of land use and abandonment, the spatial configuration of remnant forests, conservation of wildlife, hunting, harvesting, and management of forest products (Grau and Aide, 2008).

The distribution of forest patches of different ages within a landscape is a key indicator of the potential for forest regeneration on recently abandoned land (Chazdon *et al.*, 2009b). Young second-growth forests have higher rates of clearance than older second-growth forests or old-growth forests (Etter *et al.*, 2005). Many factors affect the persistence

of regenerating forests within tropical landscapes, such as soils, topography, road access, and proximity to urban areas (Crk *et al.*, 2009). In Puerto Rico, older second-growth forests occur on limestone substrates, at higher elevations, on steep slopes, farther from roads, and in areas with less pasture (Helmer *et al.*, 2008).

Although there is no simple predictor of the likelihood or pathway of forest regeneration within a tropical region, conserving intact old-growth forests or large forest fragments is the best recipe for future forest regrowth. Natural regeneration will proceed more quickly and will have a higher composition of old-growth species in areas bordering old-growth forests and in regions where flora and fauna are protected from harvesting and hunting (Chazdon *et al.*, 2009b). Conservation measures aimed at protecting a diversity of forest types are needed to ensure a long-term future for regenerating forests in tropical regions (Chazdon *et al.*, 2009a).

Glossary

\$ All \$ are US dollars unless otherwise stated.

Biodiversity The diversity and variety of life on earth.

Direct payments An exchange of money where a consumer of a service pays the provider for provision of that service.

Ecosystem services The benefits that ecosystems can provide to people.

Forest enrichment Planting trees in degraded or damaged forests to help recover forest density and/or to improve biodiversity by planting species otherwise unable to colonize and regenerate or that are threatened or vulnerable.

Global environment facility (GEF) An independent financial organization providing grants to developing countries and countries with economies in transition for projects related to biodiversity, climate change, international waters, land degradation, the ozone layer, and persistent organic pollutants.

Indirect payments An in-kind payment in the form of materials, labor, or time rather than payments of money.

Livelihood investments A nonmonetary payment to compensate for opportunity costs of a change in land use can include alternative livelihoods, alternative food sources, and education investments, among others.

Payments for ecosystem services (PES) Defined in purely economic terms as a voluntary transaction where a well-defined ecosystem service (or a land-use likely to secure that service) is 'bought' by a (minimum one) ecosystem service buyer from a (minimum one) ecosystem service provider if and only if the ecosystem service provider secures ecosystem services provision (conditionality).

Payments for watershed services A subset of PES that involves a similar financial transaction but the focus is watershed-based hydrologic services.

Revegetation Replanting grasses, bushes, and other types of vegetation on cleared and bare soils.

Introduction

Water funds are an innovative ecosystem services-based approach to conservation that use a sustainable finance mechanism created through investments by water users and other stakeholders to ensure the long-term provision of critical hydrologic services from a watershed. Investments are essentially paid into an endowment fund. Fund contributions are used to improve management of small-scale farms and ranches in the watershed and to strengthen the conservation of protected areas. Through such investments, water funds ensure the long-term protection of critical terrestrial and freshwater systems while providing a clean, reliable source of water – the key hydrologic services for the downstream water users. Tailored to local conditions, these funds are rapidly replicating throughout Latin America, most prominently in Ecuador, Colombia, and Brazil (Figure 1).

Biodiversity in Peril

Latin America and the Caribbean (LAC) are among the richest regions in biodiversity worldwide (FAO, 2011). South America alone accounts for half of the terrestrial biodiversity in the world and contains the world's most biodiversity-rich region: the eastern slope of the Andes. LAC includes some of the world's most biodiverse countries, for example, Brazil, Colombia, Ecuador, Mexico, Peru, and Venezuela (Mittermeier *et al.*, 1997; Bovarnick *et al.*, 2010), and contains one quarter of the 33 global biodiversity hotspots – regions of high species endemism and high rates of habitat loss – in only 15% of the Earth's land area. Additionally, the region contains close to 800 million hectares of forested areas (more than 35% of the world's forests), 570 million hectares of wild savannas, 700 million hectares of agricultural lands, and 27% of the planet's available drinking water. From timber and nontimber forest

products to water and nutrient regulatory services, biodiversity is of strategic importance for conservation and development in LAC.

Globally, human impacts are intensifying across Earth's lands and waters, leading to unprecedented biodiversity loss. In all, 33–50% of the Earth's land surface has been altered by the human action (Vitousek *et al.*, 1997) causing huge biodiversity losses, and declines in biodiversity are greater in fresh waters than in the most affected terrestrial ecosystems (Sala *et al.*, 2000). As a result some 10–30% of all mammal, bird, and amphibian species are threatened with extinction (Levin and Levin, 2004; Kiesecker *et al.*, 2004). Despite occupying only a tiny percentage of the planet's surface (0.8%), on a hectare-to-hectare basis, freshwater ecosystems are richer in species than the more extensive terrestrial and marine ecosystems (Revenge and Mock, 1999), and yet, freshwater habitats and species are proportionally more severely degraded and threatened than ecosystems on land or in the ocean.

Of protected areas worldwide, 20% are located in LAC (ECLAC, 2010) and are under threat due to poor governance, small budgets, and weak enforcement of legislation. One major threat is land conversion for agriculture and livestock (Barbier, 2004; CEPAL, 2005) as LAC, especially Central America and the Andes-Amazon region, has long been one of the cradles of global agriculture (Diamond, 2002; Purugganan and Fuller, 2009). Overexploitation also causes huge losses in marine and aquatic systems due to overfishing, more fleets, and permissive government incentives. Another growing cause of biodiversity loss that has not been thoroughly researched or noted is the spread of invasive species largely as a result of trade but also because of human travels via airplane or road. The roads themselves are highways for invasive species. Other threats to biodiversity include development and tourism. Direct threats to freshwater systems include dams, water abstraction, flow modification, overexploitation, overharvesting, pollution, deforestation, and invasive species (MA, 2005; Dudgeon *et al.*, 2006). Additionally, water quality and water flows are impacted by surrounding land uses.

Population growth and climate change further threaten LAC biodiversity. Population growth will require greater investments in resource development (IEA, 2007), but there is increased pressure to find ways to balance development needs with those of biodiversity conservation (Kiesecker *et al.*, 2009). Climate change could cause major ecosystems to shift and species to attempt to migrate, and indirect impacts such as storm intensity and frequency can provide further opportunities for previously nonthreatening exotic species to become invasive species. Additionally, climate change threatens to alter seasonality and annual precipitation patterns, further exacerbating threats to water resources (Vörösmarty *et al.*, 2000). For example, about 50 million people in the Andes could lack dry-season water for drinking, irrigation, sanitation, and hydropower. These threats require attention.

Freshwater systems are intimately tied to surrounding terrestrial systems, so conserving one requires conserving the other. Despite numerous efforts to protect watersheds or establish drinking water projects, few programs address the link with protected areas that were often created to protect water sources (McAlpine and Wottom, 2009; Nel *et al.*, 2009). While

evidence suggests that it is more cost effective to protect than mitigate, the costs of watershed management have been almost universally neglected in water pricing. Worse still, these costs have not been evaluated against operational costs for water treatment or investment costs for new infrastructure. Recent evidence of shrinking clean water supplies and perceived water insecurity have made businesses and water utilities look at freshwater as they never have before: a valuable good that is produced, sold, and consumed and deserves investment. Increasingly, this investment is in the form of payment for ecosystem services (PES) projects to conserve freshwater systems.

Ecosystem Services and Payment for Ecosystem Services: Rapidly Expanding Conservation Approaches

In the latter half of the 1990s, researchers began using ecosystem service values to demonstrate the importance of natural capital (e.g., Costanza *et al.*, 1997), and with the publication of the Millennium Ecosystem Assessment (MA, 2005), the importance of biodiversity to secure livelihoods became increasingly evident, particularly through the delivery of ecosystem services – the benefits that nature can provide to people (Daily, 1997). In the past decade, more studies have looked at ecosystem service values and at the biodiversity values either directly associated with ecosystem services such as the economic benefits to pollination from conservation (e.g., Ricketts *et al.*, 2004) or the indirect, all-inclusive values such as the economic benefits and costs avoided by not creating protected areas (e.g., Bezaury-Creel, 2009). These have led to an increasing understanding of the relationship between biodiversity conservation, ecosystem services, and human well-being.

Inevitably, ecosystem service approaches to biodiversity conservation will require trade-offs that might imply that the conservation of one service is done at the expense (degradation) of another (e.g., Heal *et al.*, 2001; Pereira *et al.*, 2005; Rodríguez *et al.*, 2005, 2006). Of particular interest is the possibility that the recent emphasis on ecosystem services could actually detract from biodiversity conservation. For example, if projects are designed and managed with special attention to how people benefit, will that take attention away from biodiversity (Kareiva *et al.*, 2008)? Naidoo *et al.* (2008) found that locations selected for conserving ecosystem services would conserve only 22–35% as many species as locations selected for preserving biodiversity. What's more, only 16% of World Bank biodiversity-focused development projects resulted in a win-win for biodiversity and human well-being (Tallis *et al.*, 2008). That said, optimizing an ecosystem for one or a few services can prove beneficial provided the ecosystem can function as a whole (e.g., Tallis and Kareiva, 2006). As such, ecosystem services are one of many biodiversity conservation approaches.

Despite such trade-offs, ecosystem service approaches to conservation confer advantages, not the least of which is providing opportunities for conservation in new areas. Thinking in an ecosystem services framework can broaden the scope for conservation by expanding where we view conservation opportunities and what those opportunities are (Tallis *et al.*, 2009;

Goldman *et al.*, 2008). Additionally, that approach can diversify stakeholder interest in and funding streams for conservation (Goldman *et al.*, 2008), so it is one of many useful approaches for conservation. While there is still uncertainty about what factors are likely to contribute to successful ecosystem service projects (Perrot-Maitre, 2006; Asquith and Wunder, 2008; Engel *et al.*, 2008; Jack *et al.*, 2008; Daily and Matson, 2008) and debates about their use continue (e.g., Goldman and Tallis, 2009), these approaches continue to proliferate.

Ecosystem service projects can take a wide variety of forms and serve a variety of functions (Tallis *et al.*, 2009), but in applied conservation, PES projects are widely touted as an innovative finance mechanism (Salzman, 2005; Wunder, 2007; Jack *et al.*, 2008). In the last decade, PES schemes have received considerable attention (e.g., Landell-Mills and Porras, 2002; Pagiola *et al.*, 2007; Jack *et al.*, 2008; Sommerville *et al.*, 2009) with their focus on providing financial incentives to land owners or managers whose conservation actions benefit others when those benefits would otherwise not be compensated (Sommerville *et al.*, 2009).

Payment for watershed services (PWS) projects, a subset of PES approaches, are a significant portion of ecosystem services schemes (many others relate to carbon) and often involve water users paying “suppliers” for the delivery of clean, consistent water supplies (Brauman *et al.*, 2007; Krchnak, 2007; Asquith and Wunder, 2008; Porras *et al.*, 2008). Numerous case studies of these approaches exist in the developed (e.g., Perrot-Maitre, 2006) and developing (e.g., Stanton *et al.*, 2010) world. In 2002, there were only 41 proposed and ongoing PWS schemes in developing countries (Landell-Mills and Porras, 2002), but the number more than doubled in 6 years as a recent review documented 50 ongoing, eight advanced proposals, and 37 preliminary proposals (Porras *et al.*, 2008). Both freshwater ecosystems (wetlands, aquifers, rivers, and lakes) and terrestrial ecosystems provide hydrologic services (MA, 2005) and help to regulate the quantity and quality of water accessible to people, but the value associated with this service is difficult to capture; there is no easily obtainable market value. Water funds are a mechanism that uses the value of these hydrological services to enable biodiversity conservation. Figure 1 is the map of ongoing and proposed water funds.

Water Funds: Protecting Biodiversity Through Ecosystem Service Payments

The Nature Conservancy (TNC), in collaboration with numerous partners, has successfully replicated a series of PES projects called water funds across Latin America. In these funds, payments from water users help protect the ecosystems that provide important hydrologic services and help improve management of working landscapes to ensure regular supplies of clean water. TNC has partnered with the Inter-American Development Bank (IDB), the Global Environment Facility

(GEF) and FEMSA Foundation to improve the water funds model, to further replicate it, and to explore new sources of private and public funding for watershed conservation and management. The US Agency for International Development (USAID) has been another critical partner in replicating water funds, particularly in Ecuador.

Through water funds, TNC has more than matched the rapid advancement of watershed-based ecosystem service payment schemes in the global developing world in just one region (the Northern Andes) using just one project approach. In addition to funds not supported by TNC, today there are about 45 TNC-supported water funds in some stage of development in LAC (Figure 1; Table 1) ten of which are operational. What makes the water fund model so successful? Water funds are driven by water users, and the approach has the potential to be successful in a variety of political and institutional settings throughout the world. They have many of the elements for success identified in similar schemes (Porras *et al.*, 2008; Landell-Mills and Porras, 2002) but they go beyond the basics to become truly participatory, long-term, adaptable, multi-institutional, sustainable watershed conservation projects that with strong leadership and advocacy set them apart from the others.

History of the Water Fund Concept

About 80% of the water for the city of Quito, Ecuador (nearly two million people) comes from three protected areas and their buffer zones: Cayambe-Coca Reserve, Antisana Reserve, and Cotopaxi National Park. These areas contain about 5% of Ecuador’s land area, include headwaters of more than 20 rivers and six larger watersheds, and provide critical habitat for many of Ecuador’s bird and mammal species, but a variety of activities threaten this biodiversity and the availability of the clean, regular water supply. These threats include insufficient budgets to adequately control and conserve protected areas and buffer zones to prevent ecosystem conversion, illegal logging, and deforestation, among others. Much of the pressure on the land is from the people living in the watershed, as they depend on natural resources for their livelihoods. Available productive land is diminishing as soils lose nutrients, forcing families to move up the watershed into the natural ecosystems – a mixture of forest and páramo (high altitude grasslands) – that are the key hydrologic regulators of the system. Conversion means diminishing water services to people downstream, but keeping watershed communities out is unjust and unsustainable.

In the late 1990s, with the results of the USAID- and Fundación Antisana-funded SUBIR I and II projects in hand, TNC approached the mayor of Quito to demonstrate that protecting Quito’s watersheds was crucial if citizens were to continue to enjoy the same regular supply of clean water in the future. TNC wanted to create a finance mechanism for

Figure 1 TNC water funds in Latin America and the Caribbean – mature, created, and in design. An illustration of mature, created, and in-design water funds throughout Latin American and the Caribbean where blue dots indicate mature, operational water funds; green dots indicate water funds that have been formally created but are only just starting operations; and red dots indicate water funds that are currently in the process of being designed. Data for this figure comes from Esri, DeLorme, NAVTEQ, TomTom, Intermap, iPC, USGS, FAO, NPS, NRCAN, GeoBase, IGN, Kadaster NL, Ordnance Survey, Esri Japan, METI, Esri China (Hong Kong), and the GIS User Community.

Table 1 Current status, location and number of beneficiaries of water funds projected portfolio in Latin America and the Caribbean

No	Water fund name	Country	Status of WF				Population Beneficiaries
			Idea	Feasibility	Created	Consolidated	
1	Agua por la Vida (East Cauca Valley)	Colombia					920,000
2	Cartagena	Colombia					892,545
3	Medellin	Colombia					2,700,000
4	Sierra Nevada de Santa Marta	Colombia					TBD
5	Bogota Agua Somos	Colombia					6,840,116
6	Cali	Colombia					2,100,000

Total							58,098,166.00

watershed conservation, and then Ecuador Program Director, Roberto Troya, obtained the support of the mayor, the municipality and the Quito water company (Empresa Municipal de Alcantarillado y Agua Potable de Quito – EMAAP-Q – the key water user) to do so.

The financial approach was carefully evaluated and selected because it was ecologically sustainable, legal, politically viable, efficient, and participatory (Krchnak, 2007). In January 2000, it was decided that voluntary donations from stakeholders would go into a trust fund that would form the financial basis of the water fund. The Quito Water Conservation Fund – Fondo para la Conservación del Agua or FONAG – was thus created as an endowment fund now receiving money from government, public utilities, electric companies, private companies, and nongovernment organizations. The donations

were invested and managed by an independent organization through a trust, and initially, only the interest was used to fund activities. Over time, the financial model has shifted; now some contributions go into the endowment and some immediately finance conservation activities.

FONAG initially had two main members: TNC and EMAAP-Q. Other water users have since joined such as the Quito Electric Company (La Empresa Eléctrica de Quito – EEQ) in 2001 and private organizations including a beer company (Cervecería Andina) in 2003, the Swiss Agency for Development and Cooperation (COSUDE) in 2005, and a water bottling company (Tesalia Springs Co.) in 2005. Incentives for participation vary but are complimentary. The main incentive for EMAAP-Q and the other major water users was avoiding or reducing future costs for water treatment and

supply, functions provided by the conserved ecosystems. For TNC, the incentive was long-term financing for conserving protected areas (Goldman *et al.*, 2010a).

FONAG is governed by a board of directors comprised of water users who have contributed to the fund. The board approves the annual operational plan and reports, conducts audits, and reforms the bylaws. It also has a technical secretariat that acts as executive director.

In 2004, TNC invited the mayor of Quito to visit the PES mechanism in New York City, the example upon which FONAG was created. As a result of this visit, the mayor helped support and pass a municipal ordinance dedicating 2% of water fees to FONAG. TNC and the FONAG secretariat have been instrumental in helping explain and explore the benefits nature can provide to people, in this case, hydrologic services. USAID was another critical component of FONAG's success and has been a key player in strengthening FONAG and in financing a variety of the fund's activities.

The water fund concept has been improved dramatically since FONAG. Several have used cutting-edge science to meet challenges like the funds in Bogotá and the Cauca Valley of Colombia and in the Paute watershed near Cuenca, Ecuador. New users like major hydropower companies and big agricultural producers are involved and are beginning to understand and learn about the value of nature to their business operations. TNC has proposed a model and a business plan to replicate water funds in new places around the world.

The Institutional Workings of Water Funds

Clean water is a basic human necessity: not only do people require it for drinking, but many industries require it for production including everything from electricity to beer. In many watersheds, this life-supporting service comes from surface flows and aquifers. Nowhere is this truer than in the Northern Andes region of South America. Here, surface flows from high altitude head waters supply water to diverse users most notably several large cities (e.g., Bogota and Quito), hydropower companies, and in some cases, agricultural producers. These users have a vested interest in maintaining clean, regular water flows at the lowest cost and in managing supply risks. Water funds emerged from these concerns.

Water Funds are an innovative way to pay for nature's services – clean freshwater and biodiversity – by investing in conservation projects that protect the healthy habitat from which the services derive. Each water fund has its own set of objectives and goals, but in general, they invest to: (1) improve or maintain water quality and water quantity for downstream users; (2) maintain regular flows of water throughout the year; (3) maintain or enhance natural ecosystem biodiversity, both freshwater and terrestrial; and (4) improve or maintain human well-being and quality of life for upstream human communities (Goldman *et al.*, 2010a).

Historically, water flows and water cleanliness have been naturally regulated by predictable precipitation patterns and natural vegetation, but deforestation and the degradation of natural ecosystems, increased human demand for water, and a changing climate are all threatening and disrupting the ability of ecosystems to provide these services. Thus, water purification

Figure 2 Water fund general model including financial flow and operational process. A wide variety of water users and other donors have invested money in water funds. Depending on the fund, portions of investments are directly invested in operational activities and conservation activities (protection and restoration) while the rest of the fund money is invested in an endowment fund. Capital from the endowment fund similarly funds operational and conservation activities.

and storage services are now increasingly provided by water filtration plants or regular dredging of reservoirs to remove unwanted sediments. Water funds aim to restore or maintain nature's ability to provide these critical hydrologic services. In the long run, it could be cheaper and more sustainable than investing in business as usual, that is, gray infrastructure.

Figure 2 summarizes the basic water fund model. The funds attract contributions from water users such as water utilities and local industries. These contributions build the funds' capital, including an endowment fund. In turn, endowments are invested in a wide range of assets (e.g., money market, bonds, and stocks) and the revenue generated from those investments provides long-term, secure funding for conservation projects like creating and strengthening protected areas, helping neighboring landowners switch to conservation-friendly management practices, paying for conservation easements, and financing environmental initiatives for local communities. Species benefit from having larger and better protected territories, communities benefit from a healthy watershed and improved land management, and large water users benefit from the resulting reduced water treatment costs. In addition, investments in watershed management reduce the risk of future clean water shortages that promotes long-term economic growth. With watershed conservation as a common objective, water funds create a governing body often bringing together public and private partners to manage it.

Investing in Watersheds: Providing the Hydrologic Services

Water funds invest in nature and in people by resolving potential conflicts between the resource needs of watershed communities and the conservation needs for water-service supply. Thus, investments focus on:

1. Managing public protected areas; and
2. Implementing best management practices on productive systems.

Ensuring good conservation management and providing incentives to conserve and restore natural ecosystems can provide long-term protection for the watershed but only if the incentives are sufficient to compensate people for any negative impacts.

Public Protected Area Management

The Northern Andes Region contains 20% of the World's biodiversity in an area that covers only 0.2% of the world's surface; 17% is protected and a relatively intact mixture of native forests and *páramo*. However, growing demand for land and access to resources to support livelihoods is increasingly threatening protected areas, and the level of government investment is not sufficient. For example, in 2005 according to the Ministry of Environment in Ecuador, there were 31 legally declared protected areas and there was a budget shortfall of ~\$9.5 million (all \$ as USD unless otherwise stated). For even the most basic management the gap was still ~\$3.6 million. Despite numerous efforts, few programs address the link between managing protected areas and drinking water (Echavarría, 2002; Benítez *et al.*, 2010). *Páramo*, in particular, is a crucial water regulator; disturbance can damage or destroy its hydrologic functioning (Buytaert *et al.*, 2006, 2007). Water

funds do address the link between drinking water and protected areas and can supplement budgets by cofinancing park guards, creating community-based ecotourism programs, and improving infrastructure management (Table 2). Park guards paid by the water fund are from the local communities ensuring community participation and acceptance, and providing a stable source of income for participating families.

Implementing Best Management Practices

In the watersheds, families rely on crop and ranchlands for income in and around protected areas. Managing these lands can have major impacts on water quality, the timing of flows (particularly floods), fires, and freshwater biodiversity. Water funds seek to minimize these impacts by providing direct and indirect payments to families for land management that includes setting aside conservation areas (e.g., fencing off riparian areas and headwaters), restoring and revegetating priority areas, silvopastoral management (e.g., live fences, forage plants, and rotating pastures), creating agroforestry systems, and/or creating tourism facilities (Table 2).

Specific conservation management practices supported by the water funds will vary by location, but investing in land management is essential for providing ecosystem services.

Table 2 Conservation activities of water funds

Activities	Description	Type of strategy	Relation with water and biodiversity		
			Area maintenance (conservation)	Best practices	Restorations
1. Public protected area management plan implementation					
1.1. Co-finance park guards	Improve control of high-risk conservation areas	Threat abatement			
1.2. Community-based eco-tourism programs	Reduce threats to buffer zones through income substitution	Threat abatement			
1.3. Improve infrastructure management	Support best practices on management of current and new infrastructure in the park	Threat abatement			
2. Best practices at the farm or productive unit					
2.1. Set aside conservation areas	Environmental payment for areas set aside for conservation on farmland: along streams, headwaters or forest connectivity	Conservation			
2.2. Set aside areas and restoration	Restoration payments and future environmental payments for areas set aside for conservation and restoration	Conservation			
2.3. Silvopastoral systems	Improve productivity of farm with more environmentally-friendly cattle ranching practices such as live fences, forage plants, rotation of pastures	Best practices			
2.4. Agroforestry systems	Introduce environmental practices in the farm	Best practices			
2.5. Tourism facilities	Income substitute for land use practices	Conservation			

These services can benefit the landholder (by enhancing soil stability and nutrient cycling), other people in the watershed (by providing clean and consistent water flows), as well as the broader ecosystem (by protecting habitat and biodiversity). Changing management practices is not, however, without cost. Restricting access to fertile soils in natural ecosystems and encouraging conservation management on productive lands involves trade-offs. Families are left with less land, so adequate, appropriate compensation is necessary.

The Payments: Compensating Impacts

Water funds must be flexible as they are established in geographically diverse places and in different legal and institutional settings. This includes the type of compensation provided to watershed communities. In the Northern Andes, indirect payments and livelihood investments have worked best. Indirect payments are in the form of materials and training to improve land management such as supplies for fencing and seeds for revegetation. Ideally, conservation management will enhance farm/ranch productivity by producing on-farm ecosystem services such as soil stabilization and enhanced soil fertility, but these benefits will not be immediate and are not guaranteed. In the shorter term, conservation management agreements include livelihood investments such as environmental education programs, alternative income sources like guinea pig farms, alternative food sources like organic vegetable gardens, and expanded capacity for production like building a milk bottling plant in the community to reduce shipping costs and payments for outside bottling fees, among others. As described later (*see* The Case of Brazil), in addition to indirect payments, Brazil uses mostly direct payments to landowners to compensate them for the opportunity costs of their traditional land uses.

Financial Sources and Management

Flexibility is also required in financial management, as are transparency and longevity, to ensure success under different legal and institutional frameworks. The core financial mechanism is a trust fund or endowment fund (Figure 2). This unique fiduciary structure involves an independent financial institution. A trustee (nonpartisan) manages and distributes payments to recipients (e.g., watershed communities and/or park guards) based on decisions made by the trustors, that is, the water fund board that generally comprises the main water users and other stakeholders. National and regional rules and regulations dictate the preferable investment scheme for the fund (private, nongovernment, etc.). All the trust funds have long-term contractual arrangements explicitly defining their use.

Water user contributions to the trust create a principal that accrues interest revenue for conservation projects. Ideally, the principal is untouched and only the interest is used. TNC and partners have learned, however, that in order to secure more partners and more contributions, at times it is important to use part of the principal in the first few years to demonstrate tangible progress as interest takes time to accumulate (Figure 2). Thus, the initial financial arrangement must include what percentage of the fund, if any, can be used. Some

of the water funds, Fondo del agua para la conservación de la cuenca del río Paute (FONAPA – Water Fund for the Conservation of the Paute river watershed), for example, have designated a portion of the trust to go directly to conservation activities. This makes sense in smaller watersheds that are less likely to have large capital investments earning significant interest in a reasonable time.

Water funds can be financed from a variety of private and public sources including the following:

- *Water users (e.g., water utilities, bottling companies)*: potentially the largest beneficiaries, the users are also often the largest financial contributors.
- *Citizens*: a fundraising proposal for the Bogota water fund was to get donations from citizens through their water bills. Contributions from the general public (low contribution, high volume) can be a significant source of funding.
- *Taxes, levies, and public programs*: working with existing local regulations, taxes, fees, or special-purpose contributions can be a strong source of funding. In FONAG, a municipal ordinance requires the water company to direct 2% of tariffs to the fund. In countries such as Colombia and Brazil, water laws obligate water users, municipalities, and environmental regional authorities to invest resources in the watershed, and water funds have managed to capture their interest since they leverage other money, are participatory, and can function as implementation arms for public funding. In some cases, this might be an ideal revenue source for water funds.
- *Grants, international organizations, and private foundations*: funding from bilaterals, multilaterals, or independent foundations can play a strategic role in the first 2 years of a water fund by helping to establish it including funding feasibility studies. TNC has provided this support in the past. Grants are also used to fund specific activities in the conservation plan. USAID, for example, has been very important in supporting water funds in the Andean region.
- *GEF*: funding will be directed to critical start-up costs, specifically to the endowment fund, and will co-finance outreach and feasibility studies. In Brazil, money will be spent only on technical support and conservation activities.
- Financial returns generated from the endowment fund.

Revenue sources vary from one water fund to the next depending on a variety of factors such as the legal framework for water policy, private sector opportunities, environmental service provisions, and governance strategies. Based on current experience, the majority of funding will come from the public sector and from water users. Funding through grants, international organizations, and private foundations, while proportionately small, is essential in ensuring that the water funds have a solid foundation.

Governance

Water funds are governed not by a separate nonprofit or nongovernment entity; rather, they are governed by contractual partnerships which create a collaborative, stakeholder-based, decision-making board that elects and approves

a technical secretariat that calls meetings and implements decisions. In addition, the board can establish technical committees to help guide its investment decisions. The main contributors to the fund necessarily have a voice on the board, but noncontributors and indirect contributors can also participate. For example, in the Procuenas water fund in Zamora, Ecuador, the Ministry of the Environment, a noncontributor, has a seat on the board as their input and support is essential. In Tungurahua, Ecuador, numerous, important indigenous communities in the watershed will be affected by the water fund and have invaluable knowledge about the watershed, so the German Technical Cooperation Agency GIZ donated money in their names so they have representatives on the board. TNC contributes both directly and indirectly, and in many cases has a representative on water fund boards. In the Cauca Valley in Colombia, each of the nine watersheds that feed the East Cauca Valley has a grassroots, nonprofit organization that has been working with the communities for many years. The directors of these organizations have seats on the technical committee to ensure community input.

The board sets priorities and makes decisions on investments and approves activities, but a lesson learned from FONAG was to ensure a scientific or technical basis for those decisions; thus, most are now based on feasibility or analytical studies and often on advice from a technical committee composed of scientists and engineers. The overall obligation of the board, with input from the committee(s), is to create and implement a strategic and an operational plan that include specific objectives and the means to achieve them.

How is a Water Fund Created?

While there cannot be a single formula for creating a water fund given the diversity of their features, there is a set of general steps that should be followed to establish a successful one. These steps are the result of a decade of lessons learned by TNC in replicating, improving, and advancing funds across Latin America (see *Calvache et al.*, 2012 for more detail).

Step 1: Can We Even Think About a Water Fund Here?

The first step is to determine if the right service users and service providers exist in the same area. This requires an ecosystem services assessment to determine if specific areas for generating the hydrologic services upon which a specific set of water users depends can be defined. There must be an explicit, measurable relationship between a specific area, the services the ecosystems in the area can provide, and the stakeholders in the area. Three important questions guide this step: (1) What is or are the service(s) that the water fund will prioritize for protection, conservation, restoration, and where is the long-term opportunity? (2) What is the area of influence for generating these services? and (3) Who are the key water users interested in these services, what is their interest, and how might the value of these services be internalized in their cost-benefit analyses? This type of work is best done by establishing a core working group that includes a main water user when possible.

Step 2: Will a Water Fund be Successful Here and How?

A water fund will most likely be effective if technical, financial, and legal studies are conducted beforehand to demonstrate the importance of the water fund to water users and to provide information for setting investment priorities if and when the fund is created. Determining what studies are needed is best done by creating a working group that includes the key stakeholders identified in Step 1. Work can then be divided among the participants. The detail and depth of the studies will depend to a great extent on available data and resources, but they should attempt to answer the following questions: (1) What is the demand and supply status of current hydrologic services? (2) What are the potential benefits or impacts – environmental and socioeconomic – of the water fund? (3) Where are priority areas for water fund investments? (4) What is the cost of maintaining or improving hydrologic services? (5) How will the provision of hydrologic services change as land use and climate change? and (6) What services other than hydrologic services can the water fund maintain? There are a growing number of tools (e.g., InVEST, SWAT, and ECOSAUT) to analyze the feasibility of a water fund and the potential impacts of its investments.

A final critical study is a legal and institutional assessment/analysis. Water funds ideally need to be transparent, independent, and permanent. An institutional analysis can help to identify legal hurdles and opportunities and to define the most appropriate financial and governance structure for the fund given the particularities of the country. National, regional, and local laws are all important to consider and follow in water fund design.

Step 3: Designing and Negotiating the Fund

With the stakeholder analysis and the feasibility studies in hand, the structure of the fund can be designed, contracts can be negotiated, the governance mechanism can be determined, administrative principles can be defined, and a contract can be signed. As water funds involve stakeholders from a wide variety of institutions, it is essential to have a clear definition of roles and responsibilities. The structure should be specified in a contract that formalizes the partnership. From experience, TNC has found that a useful structure is the previously described board of directors, technical secretariat, and technical committee(s). The board is a formal public-private partnership working under a mutually agreed, legal contract to ensure that each stakeholder has a role and the obligation and incentive to carry it out.

Finally, a process for handling administrative details must be determined. These include managing fund activities, the money in the fund, and other administrative matters that arise during formation and implementation.

Step 4: Details, Details, Details

Taking into account the studies in Step 2, the basic components that will allow the fund to achieve its social, environmental, economic, and institutional goals are then decided. The goal is to establish the first board of directors that will then appoint the technical secretariat. In addition, a

technical committee should be created to help guide decision making.

After these entities are functioning, the board should develop a strategic plan and a financing plan. The strategic plan lays out the basic components of the fund's operational plan that should reflect the priority areas and activities in the feasibility assessments. The strategic plan should highlight the objective of the investments, the goals and how they will be achieved, a timeline, and costs. Fundraising is a critical part of water funds particularly to finance current activities, and bringing more water users into the fund can increase the amount of money in the trust thereby enhancing sustainability.

Step 5: Activities Begin

Operationalizing the fund means executing the plans created in Step 4, that is, implementing the proposed investments and all the activities needed to achieve the goals. Execution is mainly the responsibility of the technical secretariat, but this should be supported by the technical committee that can provide advice and suggestions to improve implementation.

Actual implementation means further prioritizing activities for investment with a view to maximizing efficiency – achieving the greatest impact for least cost. Scenario-based, land-use change analyses can help determine the best activities for achieving the goals. The major activities implemented thus far by water funds have been described previously.

The financial management plan created in Step 4 should include goals and a timeline for acquiring future funding and for capitalizing the trust. Implementation includes launching communication and fundraising plans. Interest in participating in a fund can increase or decrease, so it is important to constantly attract new donors and participants.

Finally, a plan should be developed to disseminate results beyond just the stakeholders in the water fund. This can often be done by contracting a marketing and communications firm. Fundraising can also be done by contracting an appropriate organization.

Step 6: Evaluating and Monitoring

A final, but very important, step is to monitor and evaluate outcomes to ensure the goals are being achieved and to promote adaptive management. A monitoring plan is a tool to help maintain and expand the technical and financial support for the water fund effort. It should cover socio-economic, biophysical, institutional, and economic impacts. Monitoring outcomes can help to do the following: (1) ensure activities implemented are achieving desired goals; (2) make adaptive management possible allowing for changing and adjusting activities; (3) improve communications about the fund's activities and benefits; and (4) improve water fund transparency.

Examples of Water Funds: Ecuador and Colombia

As described previously, water funds are flexible ecosystem-services-based payment mechanisms adapted to different

localities, regions, and countries. The following are two examples of water funds that have succeeded in different contexts. FONAG in Quito, Ecuador was the first water fund and is now demonstrating its impact. The Water Fund for Life and Sustainability – Fondo de Agua por la Vida y la Sostenibilidad – FAVS in Colombia is a water fund in the Cauca Valley whose water users are an association of sugarcane farmers.

FONAG – Quito, Ecuador

Previously we described FONAG; here we focus on outcomes. In 2000, FONAG had \$21,000 invested in the trust fund – money from EMAAP-Q (\$20,000) and from TNC (\$1,000). By 2008, the trust fund had grown more than 250 fold to about \$5.4 million and is now (2011) nearly \$9 million. In 2008, this endowment yielded about \$800,000 in interest to spend on conservation projects (FONAG 2008). In 2007, FONAG, with the support of its board members, helped to pass a municipal bylaw requiring the Quito water company (EMAAP-Q) to provide 2% of its revenue to the water fund (an increase from the initial 1% commitment).

FONAG was initially structured so that only endowment interest was used on conservation activities along with other money leveraged by the fund but not invested in the endowment. These investments were often substantial. From its initiation through 2008, \$7.1 million was donated to FONAG as matching funds from a variety of other donors. USAID, in particular, has been one of the most important supporters of FONAG throughout; other donors include InWEnt – Capacity Building International, Germany; IDB, and EcoFund (FONAG 2008). This past year, the board decided to change the financial model and in the future, 30% of funds will be invested in implementing current and future activities and 70% will remain in the endowment.

FONAG uses the revenue from the water fund to finance various programs and projects. The programs currently underway are controlling and monitoring conservation areas, restoring natural vegetation, environmental education and outreach, training in watershed management, communications, integrated watershed management, and hydrological monitoring. The main beneficiaries of the activities are the communities close to the water sources. They receive permanent support from FONAG through various programs. From 2000 to 2010 FONAG has achieved the following:

- helped to conserve the watersheds that provide 80% of Quito's water (population of about 2 million);
- had a positive impact on 500,000 ha/1.2 million acres of land;
- enrolled 30,500 children in environmental education programs;
- enriched standing forest to improve forest density and quality on ~600 ha of land/year from 2006 to 2010;
- reforested 2033 ha/5023 acres of land with over two million trees;
- hired, trained, and salaried 11 park guards from local communities to help conserve protected areas; and
- engaged over 200 families in community development projects in rural basins.

Recent monitoring and evaluation projects have helped to demonstrate FONAG's impact. By analyzing the biodiversity of conservation areas supported by water fund investments and comparing them to areas with no such investments and a "pristine" reference site, it was found that the species composition of water fund-supported conservation areas are similar to the reference site but differ considerably from areas without water funds. There have also been reductions in grazing impacts and fire damage in several vast areas where the water fund supports protection. Finally, the analysis demonstrated that the conservation activities of the water fund helped maintain the ecology of the sites intact in an economically efficient manner (Boucher, 2011).

An analysis of water-related impacts revealed that waterways with water fund investments have greater ecological integrity, improved riparian and aquatic habitat quality, reduced erosion, and a more balanced temperature than waterways without fund investments. Additionally, the richness and diversity of macro-invertebrates in water fund waterways were greater than waterways with no water fund investments indicating better water quality and increased ecosystem integrity. These results were not true for each individual site analyzed (eight sites were compared with eight similar nonwater fund sites) which helped to demonstrate where adaptive management might be needed to ensure that more goal-appropriate activities are implemented in those areas (Encalada *et al.*, 2011).

In terms of impacts to the people living in the watershed, communities not affected by FONAG were compared socio-economically with communities affected by the water fund across a number of variables. The results revealed that communities with FONAG interventions had the following: (1) a great diversity of plant and animal species in the watershed area; (2) greater investments in subsistence farming particularly in horticulture and meats that had led to a reduction in expenditures by households in the market and increased food security; and (3) improved agricultural management. Communities impacted by FONAG also had a better understanding of their legal rights and had fewer community conflicts (Delgado and Mosquera, 2011).

As the oldest of the TNC water funds, FONAG has demonstrable results both in terms of actions implemented and outcomes. FONAG is only now developing studies to help prioritize investments; thus, the positive outcomes of the fund could potentially increase.

Fondo de Agua Por La Vida y La Sostenibilidad – Cauca Valley, Colombia

The FAVS water fund – Water for Life and Sustainability – in the Cauca Valley of Colombia lies near the city of Cali and serves a watershed that contains a huge number of sugarcane producers, an important export and domestic crop for the country. The water users are these sugarcane growers and about 900,000 people residing in cities in the watershed. As in FONAG, providing hydrologic services is dependent on conserving upstream natural ecosystems and managing the lands of rural watershed communities.

Led by TNC in June 2009, FAVS was launched by bringing together a variety of partners: ASOCAÑA (Colombia's

sugarcane producers association), CVC (Corporación Autónoma regional del Valle del Cauca, the local environmental authority), Vallenpaz (a peace and justice organization), and nine grassroots organizations representing nine subwatersheds that feed the valley. Other stakeholders have since joined including the sugarcane growers association (Procaña), the technical branch of the sugarcane association (Cenicaña), and two other grassroots organizations representing two additional subwatersheds. In 2009, the fund contained \$1.8 million in capital from the sugarcane producers association (ASOCAÑA). In the first 2 years of its operations, FAVS raised more than \$5 million from both the private and public sectors (UNICEF, PAVCO, Colombian Oil Company ECOPETROL, Regional Environmental Authority CVC, others). Current negotiations with the sugarcane growers association (Procaña) are likely to bring in an additional \$2.3 million per year to the fund.

The principle objectives of FAVS are to increase the natural vegetation in the watersheds in order to maintain their hydrologic services, to conserve biodiversity, to provide water for consumption and for industry, to irrigate lands, to provide recreation, to generate energy, and to protect fishing resources. The Cauca Valley has the most productive sugarcane land in the world; damage to the region's forests and water resources threatens to reduce production significantly, which could cost the industry \$33 million each year, according to the sugarcane producers association (ASOCAÑA) (based on TNC estimates of water yield and climate change that basically indicate that the length of irrigation cycles will decrease).

Activities in the watersheds that the fund is helping to support include isolating riparian areas to keep cattle and crops from riversides, protecting headwaters, reforestation and restoring landscapes, revegetating pasturelands, and conserving natural ecosystems. Ultimately the aim is to conserve and restore about 30,000 ha of land. In addition, through livelihood investments the water fund is promoting food security for local communities, environmental education, and capacity building to ensure sustainable production. FAVS aims to benefit 1500 families directly and to help provide water for 1.25 million people. To date, FAVS has spent more than \$1.4 million on conservation projects: \$0.1 million on the first water fund project; \$0.6 million in the first call for proposals cycle and \$0.7 million in the second proposal cycle. With these investments, FAVS has built more than 80 km of protected river fences; protected more than 87 headwaters; conserved over 250 ha of land through restoration and natural regeneration; converted more than 80 ha of critical land along streams to sustainable cattle ranching, supported the Las Hermosas Natural Park, supported nine schools by promoting environmental education, and supported at least 24 families.

FAVS has also helped to demonstrate the feasibility and importance of doing analytical studies to set priorities for water fund investments. In addition, it was the first water fund to test a methodology for ensuring that priorities for activities were based on cost and return on investment. The goal was to identify priority areas for FAVS investment, establish quantitative ecosystem service goals, and develop a portfolio of the most efficient activities. To achieve it TNC and partners used a watershed scoring process and a modeling tool called InVEST (Integrated Valuation of Ecosystem Services and Trade-offs),

developed by the Natural Capital Project (Tallis *et al.*, 2010). This evaluation involved several steps. First, a conservation activity (forest enrichment, reforestation, fencing, or silvo-pastoral practices) was assigned to each part of the landscape based on the behavior of landowners in the region and successful investments made in the watershed over the last 20 years. These assignments implicitly considered factors such as opportunity costs and land owners' willingness to change their activities (this willingness was evaluated in collaboration with the watershed grassroots community organizations). The landscape was ranked to highlight the places where possible conservation investments were likely to yield the greatest improvement in water yield and erosion control. Factors included in the ranking were those known to affect the hydrological response of the services such as slope, soil depth, distance to stream or water body, aspect, elevation and precipitation. Data from historic conservation investments in each watershed were used to estimate how much the proposed conservation activity in each location would cost (Goldman *et al.*, 2010b).

Then the landscape ranking and cost information were combined to select the highest ranked locations for each activity, tallying costs until the target budget level was met. The activities selected across the landscape formed the water fund's investment portfolio. This process was repeated for five budgets ranging from the level of investment currently committed by the fund (\$10 million) to double that amount. With this set of investment portfolios as scenarios for future management, InVEST was used to estimate the ecosystem service returns from each (Goldman *et al.*, 2010b), specifically for erosion and annual water yield providing preliminary estimates of return on investment. The model provides a relative change (%) expected as spending progresses. One of the model's results demonstrated that for one watershed, erosion control benefits would increase from 1% in year 1 to 14% in year 5 based on water fund investments (The Natural Capital Project, 2011). Basically, InVEST helps to determine the most efficient investment portfolio for providing the two main services of interest: annual water yield and avoided sedimentation.

Work is now being done on this water fund to incorporate the impacts of climate change into the scenarios and the activity assessment. This impact assessment helps to determine if current activities promoted by the water fund are adapted for climate change and will allow for the design of activities to promote resilient ecosystems (Goldman *et al.*, 2010a). In particular, new ecosystem services maps incorporating suggested changes based on climate vulnerabilities were prepared and discussed with key stakeholders. These maps will complement the water fund portfolio in order to make sure that FAVS activities will be aligned with climate change analysis. This information was complemented with a local expert's suggestions in terms of the main problems related to land management and best practices. A complete conceptual model was developed for this workshop with local communities to help them to understand the links between land use practices and problems derived from climate change, and priority strategies for climate change adaptation were identified.

Not only did FAVS use studies to guide the investments of the water fund, but the fund also includes community

members on the governing board. The watersheds that feed the Cauca Valley have suffered extreme levels of violence and disruption in the last decade; thus, providing the communities with a voice in how the fund operates ensures sustainability and equity. FAVS is also unique in that the main water users are agricultural producers, which demonstrates the potential for including a variety of stakeholders in water funds. A final characteristic that contributed to the fund's success is that investments are building on a legacy of watershed conservation projects already underway in the region funded by ASOCAÑA in collaboration with the grassroots community organizations. The water fund is helping to formalize and expand these prior investments by bringing the water users and providers together in a partnership to ensure joint decision making and scientifically sound investment choices.

The Case of Brazil

In the Atlantic Forest and other biomes of Brazil, TNC and partners have had great success in replicating a similar watershed conservation model called the water producer concept that has now been added to the water fund portfolio of TNC (*see* Water Fund Platform). The water producer concept was first developed by the National Water Agency (ANA) and first implemented by ANA, TNC, and several state and local partners. It recognizes the positive externalities generated by landowners living in the headwaters of watersheds when they implement forest and soil conservation and restoration activities and that people downstream benefit from these positive externalities. The concept is based on the premise that those who benefit should pay directly for that which benefits them, in this case watershed conservation. Thus landowners are compensated for their opportunity costs for generating the hydrologic services downstream users require.

Brazil's Atlantic Forest is the most densely populated region in Latin America as it is home to 11 major cities including Sao Paulo and Rio de Janeiro and 70% of Brazil's population. Since 2006, TNC and partners have been working in the watersheds of the Atlantic Forest that provide 50% of Sao Paulo's drinking water and 80% of Rio de Janeiro's. Brazil holds more water than any nation, but only 1/12 of that water can be found along the southeastern coast where nearly half of the population lives (Bradley, 2010). The forest is also one of the most biodiverse areas on earth, with 5% of the earth's vertebrates and 8% of the planet's plants. Unfortunately, much of the forest is becoming rapidly degraded and only 12% remains. Clearing and fragmentation is the main threat to its viability in the long term.

Deforestation threatens the provision of a clean, reliable water supply and signals an urgent need to protect and restore Brazil's Atlantic Forest. Water producer projects involve direct payments from water users that go toward maintaining and enhancing watershed forest cover. The incentive for water users is sustainable clean, regular water supplies at a lower cost. In Sao Paulo, for example, pollution and sediment in the water have doubled treatment costs in 8 years (Bradley, 2010). Investments in reforestation provide a natural pollution and sediment filtration system that can help curb these costs in the future.

The implementation of water producer projects in Brazil has followed three main routes (Veiga and Gavalvão, 2011). The first one is a result of the National Water Policy that established a water-user fee and required the proceeds to go toward maintaining and increasing watershed health. In addition, it created watershed committees that comprise water users and representatives of governments and civil society and have the legal power to decide the best way to spend the proceeds. The implementation of the policy and the creation of the watershed committees is ongoing gradually throughout Brazil and has started with more urbanized states such as São Paulo, Minas Gerais and Rio de Janeiro where the water-use conflicts are more prominent. The fundraising potential of these watershed schemes is significant. One example is the Piracicaba-Capivari-Jundiá Watershed (PCJ), one of Brazil's key watersheds, which raises approximately \$25 million per year in water user fees.

Creating a water producer project from this policy arrangement involves several steps. The concept is presented to the watershed committees as one of the best investments that the committee could make to guarantee water in quality and quantity from the watersheds in their jurisdiction by explaining that the concept is based on direct payments to compensate watershed landowners for the positive externalities they generate when they restore and protect their lands. The first water producer project created this way began in 2006 in the PCJ Watershed where the watershed committee allocated \$250,000 for a first pilot in the watershed matching the funds allocated by a coalition of partners including ANA, the Environmental and Agricultural State Agencies of São Paulo State (SMA-SP and SAA-SP), and TNC (Veiga, 2009). These same partners created a project management unit that manages the pilot and creates plans for its replication within the watershed. Since this first pilot, more initiatives have been replicated in PCJ and other watersheds in the country, including the Guandu Watershed which provides water for the Rio de Janeiro metropolitan area.

A second means by which water producer projects have been created requires municipal and state legal approval explicitly for developing PES schemes. These laws are important for two reasons. They can provide a legal framework for PES implementation, and they can enable and facilitate the use of public funds for PES schemes. For example, one water producer project was based on a 2005 law in Extrema, Minas Gerais, that gave the municipality the ability to pay landowners who achieved specific targets related to soil conservation measures, rural sanitation, and forest conservation and restoration. In addition, this law allowed the first direct payment to a water producer to be made in Brazil in February, 2007. This initiative was a partnership between the municipality, ANA, the State Forestry Agency, and TNC, and support was also received from the PCJ watershed committee. In addition to direct payments for environmental services, the landowners also receive financial, technical, and in-kind support to reach conservation targets. Another example at the state level occurred in 2008 in Espírito Santo where a law was passed that created a water fund called FUNDÁGUA that was primarily funded by a percentage of the oil royalties collected by the state. FUNDÁGUA stipulates that most of the fund's revenues should go toward paying landowners in

priority watersheds for the water services they provide. The first payments started in March 2009; by July 2011 approximately 300 landowners received direct payments from FUNDÁGUA.

With these examples, several other municipalities and states have been discussing and implementing laws and PES programs. TNC has been a partner in nearly all of the initiatives, especially those at the state level realizing the great potential these mechanisms have to conserve watersheds throughout the region. At the federal level in Brazil, there is a PES bill proposal under discussion at the National Congress that was informed by these first municipal and state initiatives.

A third means through which a water producer project has been created is more similar to the water funds in other parts of Latin America and has emerged more recently in Brazil. Here a key water user such as a water utility company takes the lead to implement a PES scheme. One example is a project headed by the Balneário Camboriú Municipality Water utility (EMASA), located in one of the most important touristic cities in Southern Brazil. This utility understood the benefits of investing in watershed conservation to reduce its water treatment costs and so has allocated \$1.5 million to the PES scheme. Using other water fund projects as examples, the utility and their partners (the municipalities of Camboriú, Balneário Camboriú, ANA, TNC, and the local watershed committee, among others) intend to create a municipal PES water fund to guarantee the initiative's sustainability in the long term. These schemes are also starting to be replicated. For example, SANEATINS, the water utility company of Palmas, the capital of Tocantins state, is now initiating a water fund.

A final, very nascent method for creating a PES scheme similar to a water fund in Brazil involves companies that are trying to offset their water footprints. One mechanism by which they can offset water consumption could be to invest in a water producer project. This possibility is still under development but can be considered another important source of funding for the long term, especially if the project is set up like other water funds in Latin America.

In short, the financial mechanisms in Brazil are slightly different from those of the water funds of the Northern Andes region. In general, however, the funds use an annual distribution model where fees or other sources of funding are collected and distributed each year rather than going into a trust. The payments are direct and are used to both conserve standing forest and to reforest critical areas, and they are generally based on opportunity costs to the farmer from having to reforest and/or protect and/or improve management of their land. Payments tend to range from \$29–\$100 per acre per year depending on the project site and on institutional arrangements. There are additional criteria that are specific to the sort of scheme proposed such as a landowner's willingness to participate, slope intensity, and forest quality among others that can be combined with opportunity costs. The water fund supplies materials and capacity (hiring local people) to enable reforestation. Restoration costs also vary but are round \$1600 to \$2800 per acre. The landowner's responsibility is to protect and maintain reforested or forested areas in exchange for a payment based on the location and size of restored and/or conserved parcels.

Water Fund Platform

With all the valuable experience it has gained in developing diverse approaches to watershed conservation through PES schemes, TNC in collaboration with three main partners – IDB, GEF, and FEMSA Foundation, the largest Coca-Cola bottling company in the world – is launching a water fund platform. Using this platform, the characteristics of the water funds in the Northern Andes and the PES approaches in Brazil will be extended to water funds more broadly throughout Latin America, thereby conserving and enhancing valuable freshwater and terrestrial biodiversity while providing important hydrologic services to people.

In the next 5 years TNC and its partners under the Latin American Water Funds Partnership aim to create, implement and capitalize at least 32 water funds (Figure 1; Table 1). This will comprise investments of over \$27 million to protect seven million acres of water sheds in Ecuador, Colombia, Peru, Brazil, Mexico and other countries in the LAC region (Marx, 2011).

The goals of the platform include the following:

- a total of 32 self-sustaining water funds of which 20 are new;
- conservation of more than seven million acres of important ecosystems;
- effective mechanisms for adapting natural ecosystems that supply water to climate change;
- secure access to water supply for more than 50 million people, industries, and rural areas;
- savings in water treatment costs and reduced productivity loss because of water shortages and reductions in energy supply in rural areas and for industries;
- water funds capitalized with at least \$27 million (total across all funds) from public and private local funds after 5 years;
- at least \$143 million in conservation projects, total across all water funds, on watersheds leveraged from other institutions.

As of December 2011, the platform encompassed 45 water funds in various stages of implementation (Figure 1; Table 1), most of which were just starting operations or were in the initial stages of assessing feasibility and viability.

Glossary

Mitigation wetland Wetland created, restored, or enhanced to replace lost wetlands.

Wetland Land that is saturated with water long enough to promote wetland or aquatic processes as indicated by poorly drained soils, hydrophytic vegetation, and various kinds of biological activity, which are adapted to a wet environment.

Wetland bank A site where wetlands and/or other aquatic resources are restored, created, enhanced, or in exceptional

circumstances, preserved expressly for the purpose of providing compensatory mitigation in advance of authorized impacts to similar resources.

Wetland creation The conversion of a persistent upland or shallow water area into a wetland by human activity.

Wetland restoration The return of a wetland from a disturbed or altered condition caused by human activity to a previously existing condition.

Introduction

Wetlands have been described as “ecological supermarkets” because of the extensive food chain and rich biodiversity that they support (Mitsch and Gosselink, 2007). They play major roles in the landscape by providing unique habitats for a wide variety of flora and fauna. They support a wide variety of plant, and microbial species where the “critters” come from both terrestrial and deepwater aquatic systems to reproduce, find refuge, eat, or be eaten. More recently, wetlands are being described as important water-quality enhancement ecosystems and flood mitigation systems (“nature’s kidneys”) and carbon sinks and climate stabilizers on a global scale. These ecosystem services of wetlands are now recognized worldwide and have led to wetland conservation, protection laws, regulations, and management plans. Wetlands have become the *cause célèbre* for conservation-minded people and organizations throughout the world, in part, because they have become symptoms of our systematic dismantling of the world’s water resources and in part because their disappearance represents an easily recognizable loss of natural areas to economic “progress.” But there is optimism by some that wetlands can be created and restored and that the ecosystem services such as biodiversity protection can be thus restored. Loss rates of wetlands around the world and the subsequent recognition of wetland values have stimulated restoration and creation of these systems (Mitsch and Jørgensen, 2004).

Wetland restoration involves returning a wetland to its original or previous wetland state, whereas wetland creation involves conversion of uplands or shallow open-water systems to vegetated wetlands. Wetland restoration and creation can occur for replacement of habitat, for coastal restoration, and for restoration of mined peatlands. Generally, wetland restoration and creation first involve establishment or re-establishment of appropriate natural hydrologic conditions, followed by establishment of appropriate vegetation communities. Although many of these created and restored wetlands have become functional, there have been some cases of “failure” of created or restored wetlands generally caused by a lack of proper hydrology. Creating and restoring wetlands

needs to be based on the concept of self-design whereby any number of native propagules can be introduced, but the ecosystem adapts and changes itself according to its physical constraints, and success should not solely be determined by specific plant and animal presence.

Definitions

Wetlands have many distinguishing features, the most notable of which are the presence of standing water for some period during the growing season, unique soil conditions, and organisms, especially vegetation, adapted to or tolerant of saturated soils. Wetlands are unique because of their hydrologic conditions and their role as ecotones between terrestrial and aquatic systems. Terms such as swamp, marsh, fen, and bog have been used in common speech for centuries to define wetlands and are frequently used and misused at present. Formal definitions have been developed by several federal agencies in the US, by scientists in Canada and the US, and through an international treaty known as the Ramsar Convention. These definitions include considerable detail and are used for both scientific and management purposes.

The most common definition of wetlands used in the world is the one developed as part of the Convention on Wetlands of International Importance Especially as Waterfowl Habitat, better known as the Ramsar Convention:

areas of marsh, fen, peatland or water, whether natural or artificial, permanent or temporary, with water that is static or flowing, fresh, brackish, or salt including areas of marine water, the depth of which at low tide does not exceed 6 m.

This definition, which was adopted at the first meeting of the convention in Ramsar, Iran, in 1971, states that wetlands may incorporate riparian and coastal zones adjacent to the wetlands and islands or bodies of marine water deeper than 6 m at low tide lying within the wetlands. This definition does not include vegetation or soil and extends wetlands to water depths of 6 m or more, well beyond the depth usually

considered wetlands in the US and Canada. The rationale for such a broad definition of wetlands is based on its original intention to include habitats for water birds.

In North America, there are at least five separate word definitions of wetlands (see Mitsch and Gosselink, 2007 for a summary of all). The one that is used to legally protect and define wetlands in the USA is the so-called US Army Corps of Engineering definition:

The terms "wetlands" means those areas that are inundated or saturated by surface or groundwater at a frequency and duration sufficient to support and that under normal circumstances do support a prevalence of vegetation typically adapted for life in saturated soil conditions. Wetlands generally include swamps, marshes, bogs, and similar areas. (33 CFR 328.3(b); 1984)

Canada has developed a specific national definition of wetlands that may be the best of all:

land that is saturated with water long enough to promote wetland or aquatic processes as indicated by poorly drained soils, hydrophytic vegetation, and various kinds of biological activity, which are adapted to a wet environment. (Zoltai and Vitt, 1995; Warner and Rubec, 1997)

It is illustrative that the first two definitions above retreat to common terminology used to define wetlands such as "marsh," "fen," "peatland," "swamp," and "bog." Table 1 lists many of the common terms that are used around the world to define wetlands. These common terms have specific meanings to scientists yet are widely used by the public, often well beyond the generally accepted scientific definitions. In some cases, words such as "swamp" have different meanings in North America and Europe. "Wetland" is a relatively new term in the scientific literature (one of the first uses of it was in a US Fish and Wildlife publication in 1956), but wetland definitions now abound, but there is not one that will prove satisfactory to all users (Mitsch and Gosselink, 2007). Different definitions have been formulated by geologists, soil scientists, hydrologists, botanists, ecologists, economists, political scientists, public health scientists, lawyers, and the public at large. Wetlands are not easily defined, especially for legal purposes, because they have a considerable range of hydrologic conditions, because they are found along a gradient at the margins of well-defined uplands and deepwater systems, and because of their great variation in size, location, and human influence (Figure 1). No absolute answer to "What is a wetland?" should be expected, but a combination of the three definitions above is more than sufficient to provide adequate description of wetlands from a structural and functional views.

Global Extent of Wetlands

The extent of the world's wetlands is generally thought to be from 5 to 9 million km² or about 4–6% of the land surface of the Earth (Table 2). Estimated areas of wetlands in parts of North America are fairly robust with 43.6 million ha in the lower 48 states, 71 million ha in Alaska, and 127 million ha in Canada; these collectively represent about 30% or more of the world's wetlands. The loss of wetlands in the world caused by

humans is difficult to determine, but it is probably similar to the 50% loss rate estimated for the lower 48 states of the US, with high rates of loss in Europe and parts of Australia, Canada, and Asia.

Threats to Wetlands

Wetland impacts have included both wetland alteration and wetland destruction. In earlier times, wetland drainage was considered the only policy for managing wetlands in the western world. With over 70% of the world's population living on or near coastlines, coastal wetlands have long been destroyed through a combination of excessive harvesting, hydrologic modification and seawall construction, coastal development, pollution, and other human activities. Likewise, inland wetlands have been continually affected, particularly through hydrologic modification and agricultural and urban development. By 1985, 56–65% of wetlands in North America and Europe, 27% in Asia, 6% in South America, and 2% in Africa had been drained for intensive agriculture. Other human activities such as forestry, stream channelization, aquaculture, dam, dike, and seawall construction, mining, water pollution, and groundwater withdrawal all had impacts, some severe, on wetlands (Table 3). Wetlands are degraded and destroyed indirectly as well through alternation of sediment patterns in rivers, hydrologic alternation, highway construction, and land subsidence. Wetlands are also managed close to their natural state for certain objectives such as fish and wildlife enhancement, agricultural and aquaculture production, water-quality improvement, and flood control. Management of wetlands for coastal protection has now taken on more significance.

Wetland Creation and Restoration

The literature on wetland creation and restoration has exploded like no other wetland topic. Mitsch (1994) and Streever (1999) provided early regional overviews and case studies of wetland restoration from around the world. Some general principles and details of techniques are included in the book *Ecological Engineering and Ecosystem Restoration* (Mitsch and Jørgensen, 2004). A critique of the policies and techniques of wetland creation and restoration in the US was published as NRC (2001).

Wetland restoration refers to the return of a wetland from a disturbed or altered condition caused by human activity to a previously existing condition. The wetland may have been degraded or hydrologically altered and restoration then may involve reestablishing hydrologic conditions to re-establish previous vegetation communities. *Wetland creation* refers to the conversion of a persistent upland or shallow water area into a wetland by human activity. *Wetland enhancement* refers to a human activity that increases one or more functions of an existing wetland. One type of created wetland, a *constructed wetland*, refers to a wetland that has been developed for the primary purpose of contaminant or pollution removal from wastewater or runoff. This last type of wetland is also referred to as a *treatment wetland*.

Table 1 Common terms used for various wetland types in the world

Billabong	– Australian term for a riparian wetland that is periodically flooded by the adjacent stream or river.
Bog	– A peat-accumulating wetland that has no significant inflows or outflows and supports acidophilic mosses, particularly <i>Sphagnum</i> .
Bottomland	– Lowland along streams and rivers, usually on alluvial floodplains, that is periodically flooded. When forested, it is called a bottomland hardwood forest in the southeastern and eastern US.
Carr	– Term used in Europe for forested wetlands characterized by alders (<i>Alnus</i>) and willows (<i>Salix</i>).
Cumbungi swamp	– Cattail (<i>Typha</i>) marsh in Australia.
Dambo	– A shallow treeless wetland in which water collects in the rainy season; term is used in southern Africa.
Delta	– A wetland–river–upland complex located where a river forms distributaries as it merges with the sea; there are also examples of inland deltas such as the Peace–Athabasca Delta in Canada and the Okavango Delta in Botswana.
Fen	– A peat-accumulating wetland that receives some drainage from surrounding mineral soil and usually supports marshlike vegetation.
Lagoon	– Term frequently used in Europe to denote a deepwater enclosed or partially opened aquatic system, especially in coastal delta regions.
Mangal	– Same as mangrove.
Mangrove	– Subtropical and tropical coastal ecosystem dominated by halophytic trees, shrubs, and other plants growing in brackish to saline tidal waters. The word “mangrove” also refers to the dozens of tree and shrub species that dominate mangrove wetlands.
Marsh	– A frequently or continually inundated wetland characterized by emergent herbaceous vegetation adapted to saturated soil conditions. In European terminology, a marsh has a mineral soil substrate and does not accumulate peat. See also Tidal freshwater marsh and salt marsh.
Mire	– Synonymous with any peat-accumulating wetland (European definition); from the Norse word “myrr.” The Danish and Swedish word for peatland is now “mose.”
Moor	– Synonymous with peatland (European definition). A highmoor is a raised bog; a lowmoor is a peatland in a basin or depression that is not elevated above its perimeter. The primitive sense of the Old Norse root is “dead” or barren land.
Muskeg	– Large expanse of peatlands or bogs; particularly used in Canada and Alaska.
Oxbow	– Abandoned river channel, often developing into a swamp or marsh.
Pakihi	– Peatland in southwestern New Zealand dominated by sedges, rushes, ferns, and scattered shrubs. Most pakihi form on terraces or plains of glacial or fluvial outwash origin and are acid and exceedingly infertile.
Peatland	– A generic term of any wetland that accumulates partially decayed plant matter (peat).
Playa	– An arid- to semiarid-region wetland that has distinct wet and dry seasons. Term used in the southwest US for marshlike ponds similar to potholes, but with a different geologic origin.
Pocosin	– Peat-accumulating, nonriparian freshwater wetland, generally dominated by evergreen shrubs and trees and found on the southeastern Coastal Plain of the US. The term comes from the Algonquin for “swamp on a hill.”
Pothole	– Shallow marshlike pond, particularly as found in the Dakotas and central Canadian provinces, the so-called prairie pothole region.
Raupo swamp	– Cattail (<i>Typha</i>) marsh in New Zealand.
Reedmace swamp	– Cattail (<i>Typha</i>) marsh in the UK.
Reedswamp	– Marsh dominated by <i>Phragmites</i> (common reed); term used particularly in Europe.
Riparian ecosystem	– Ecosystem with a high water table because of proximity to an aquatic ecosystem, usually a stream or river. Also called bottomland hardwood forest, floodplain forest, bosque, riparian buffer, and streamside vegetation strip.
Salt marsh	– A halophytic grassland on alluvial sediments bordering saline water bodies where water level fluctuates either tidally or nontidally.
Sedge meadow	– Very shallow wetland dominated by several species of sedges (e.g., <i>Carex</i> , <i>Scirpus</i> , and <i>Cyperus</i>).
Slough	– An elongated swamp or shallow lake system, often adjacent to a river or stream. A slowly flowing shallow swamp or marsh in the southeastern US (e.g., cypress slough). From the Old English word “sloh” meaning a watercourse running in a hollow.
Swamp	– Wetland dominated by trees or shrubs (US definition). In Europe, forested fens and wetlands dominated by reed grass (<i>Phragmites</i>) are also called swamps (see Reedswamp).
Tidal freshwater marsh	– Marsh along rivers and estuaries close enough to the coastline to experience significant tides by nonsaline water. Vegetation is often similar to nontidal freshwater marshes.
Turlough	– Areas seasonally flooded by karst groundwater with sufficient frequency and duration to produce wetland characteristics. They generally flood in winter and are dry in summer and fill and empty through underground passages. Term is specific for these types of wetlands found mostly in western Ireland.
Vernal pool	– Shallow, intermittently flooded wet meadow, generally typical of Mediterranean climate with dry season for most of the summer and fall. Term is now used to indicate wetlands temporarily flooded in the spring throughout the US.
Vleis	– Seasonal wetland; term used in southern Africa.
Wad (pl. Wadden)	– Unvegetated tidal flat originally referring to the northern Netherlands and northwestern German coastline. Now used throughout the world for coastal areas.
Wet meadow	– Grassland with waterlogged soil near the surface but without standing water for most of the year.
Wet prairie	– Similar to a marsh but with water levels usually intermediate between a marsh and a wet meadow.

Significant efforts now focus on the voluntary restoration and creation of wetlands. Part of the interest in wetland creation and restoration stems from the fact that we are losing or have lost much of this valuable habitat. Often interest is less voluntary and more in response to government policies such as “no net loss” in the US that require the replacement of

wetlands for those unavoidably lost. New Zealand, which has lost 90% of its wetlands, has made major efforts to restore marshes and other wetlands in the Waikato River Basin on North Island and in the vicinity of Christchurch on South Island. In southeastern Australia, restoration of the Murray–Darling watersheds, particularly the riverine

Figure 1 Position and function of wetlands in the landscape between terrestrial and deepwater aquatic ecosystems. Reprinted from Mitsch WJ and Gosselink JG (2007) *Wetlands*, 4th edn., 582 pp. New York: John Wiley & Sons, Inc.

Table 2 Estimated area of wetland ecosystem types in the world

Type of wetland	Area, $\times 10^6$ ha
Coastal wetlands	
Tidal salt marshes	10*
Tidal freshwater marshes	2*
Mangrove wetlands	24
Inland wetlands	
Freshwater marshes	95
Freshwater swamps and riparian forests	109
Peatlands	350
Total	580

*Number estimated.

billabongs, has become a major undertaking, while coastal plain wetland restoration and creation are occurring in southwestern Australia. There are concerted efforts to restore mangrove forests in the Mekong Delta of Vietnam, along South American coastlines where shrimp farming has destroyed thousands of hectares of mangroves and around the Indian Ocean to provide tsunami and typhoon protection for coastal areas. Tidal marshes have been created along much of China's eastern coastline, and restoration is now occurring in the Yangtze Delta in Shanghai. Wetland restoration and creation are being proposed or implemented on very large scales to prevent more deterioration of existing wetlands (Everglades in Florida), to mitigate the loss of fisheries (Delaware Bay in

Eastern USA), to reduce land loss and provide protection from hurricanes (Mississippi Delta in Louisiana), to stabilize a watershed and provide water-quality improvement (Skjern River, Denmark), and to solve serious cases of overenrichment of coastal waters (Baltic Sea in Scandinavia; Gulf of Mexico in USA).

Mitigating Wetland Habitat Loss

Wetland protection regulations in the US and now elsewhere have led to the practice of requiring that wetlands be created, restored, or enhanced to replace wetlands lost in developments such as highway construction, coastal drainage and filling, or commercial development. This is referred to as the process of "mitigating" the original loss, and these "new" wetlands are often called *mitigation wetlands* or *replacement wetlands*. Replacement wetlands are designed to be at least of the same size as the lost wetlands, but more often a *mitigation ratio* is applied so that more wetlands are created and/or restored than are lost. For example, a mitigation ratio of 2:1 means that 2 ha of wetlands will be restored or created for every hectare of wetland lost to development. Considerable controversy exists, for example, in the US, on the question as to whether wetland loss can be mitigated successfully or if it is essentially impossible (NRC, 2001). Robb (2002) reviewed several years' efforts of mitigating wetland loss in Indiana and suggested, based on failure rates of various wetland types, that there should be the following mitigation ratios: 3.5:1 for forested wetlands; 7.6:1 for wet meadows, 1.2:1 for freshwater marshes, and 1:1 for open-water systems.

Table 3 Human actions that cause direct and indirect wetland losses and degradation in the world

<i>Cause</i>	<i>Estuaries</i>	<i>Floodplains</i>	<i>Freshwater marshes</i>	<i>Lakes/Littoral zone</i>	<i>Peatlands</i>	<i>Swamp Forest</i>
<i>Cause direct wetland losses and degradation</i>						
Agriculture, forestry, mosquito control drainage	xx	xx	xx	x	xx	xx
Stream channelization and dredging; flood control	x		x			
Filling – solid-waste disposal; roads; development	xx	xx	xx	x		
Conversion to aquaculture/mariculture	xx					
Dikes, dams, seawall, levee construction	xx	x	x	x		
Water pollution – urban and agricultural	xx	xx	xx	xx		
Mining of wetlands of peat and other materials	x	x		xx	xx	xx
Groundwater withdrawal		x	xx			
<i>Cause indirect wetland losses and degradation</i>						
Sediment retention by dams and other structures	xx	xx	xx			
Hydrologic alteration by roads, canals, etc.	xx	xx	xx	xx		
Land subsidence due to groundwater, resource extraction, and river alternations	xx	xx	xx			

xx, common and important cause of wetland loss and degradation; x, present but not a major cause of wetland loss and degradation. Blank indicates that effect has not been validated.

Source: Reproduced from Dugan P (1993) *Wetlands in Danger*, 192 pp. London: Reed International Books.

One of the most interesting strategies that the private sector and government agencies have developed to deal with the piecemeal approach to mitigation of wetland loss is the concept of a *mitigation bank*. A mitigation bank is defined as “a site where wetlands and/or other aquatic resources are restored, created, enhanced, or, in exceptional circumstances, preserved expressly for the purpose of providing compensatory mitigation in advance of authorized impacts to similar resources” (*Federal Register*, 28 November 1995, “Federal Guidance for the Establishment, Use, and Operation of Mitigation Banks”). In this approach, wetlands are built in advance of development activities that cause wetland loss, and credits of wetland area can be sold to those who are in need of mitigation for wetland loss. Banks are seen as a way of streamlining the process of mitigating wetland loss and, in many cases, providing a large, fully functional wetland rather than small, questionable wetlands near the site of wetland loss.

Wetland Conservation Programs in Agricultural Lands

Conservation programs are now in place to encourage individual farmers in the US to restore wetlands on their land. Both the Conservation Reserve Program (CRP) and the Wetlands Reserve Program (WRP) under the US Department of Agriculture have led to significant areas of wetlands being restored or protected. CRP guidelines, announced in 1997, give increased emphasis to the enrollment and restoration of *cropped wetlands*, that is, wetlands that produce crops but serve wetland functions when crops are not being grown. The CRP also encourages wetland restoration, particularly through hydrologic restoration. In the CRP, participants voluntarily enter into contracts with the US Department of Agriculture to enroll erosion-prone and other environmentally sensitive land in long-term contracts for 10–15 years. In exchange, participants receive annual rental payments and a payment of up to 50% of the cost of establishing conservation practices. The WRP is another voluntary program established in 1990 and is

specific for wetland restoration; it offers landowners the opportunity to protect, restore, and enhance wetlands on their property and provides funds for the farmer to do so.

Forested Wetland Restoration

There is less experience at forested wetland restoration and creation compared to herbaceous marshes, despite the fact that these wetlands have been lost at alarming rates. Forested wetland creation and restoration are different from marsh creation and restoration because forest regeneration takes decades rather than years to complete, and there is more uncertainty about the results. Much riparian forest restoration in the US has centered on the lower Mississippi River alluvial valley, where more than 78,000 ha were reforested by federal agencies over the 10-year period 1988–1997 (King and Keeland, 1999), primarily with bottomland hardwood species and, to a lesser extent, deepwater swamp species. This is a small contribution to the restoration of this alluvial floodplain where 7.2 million ha of bottomland hardwood forest were estimated to have been lost (Hefner and Brown, 1985).

Hydrologic and Water Quality Restoration of Watersheds

Lines often blur between wetlands created and restored for habitat restoration and those restored for water quality and hydrology improvement. In fact most wetlands that are restored or created are done so for both habitat recreation and for other ecosystem services. Four large freshwater wetland restorations around the world are presented as case studies here. One of the largest wetland restoration projects in the world is the Florida Everglades where an attempt is made to restore, at least to some degree, the natural hydrologic conditions in the Everglades that are left (see Case Study 1). Another example of a proposed watershed restoration is a large-scale wetland and riparian forest restoration and

Figure 2 Florida Everglades in historic conditions, current conditions, and planned restoration conditions. Reprinted from Mitsch WJ and Jørgensen SE (2004) *Ecological Engineering and Ecosystem Restoration*, 411 pp. New York: John Wiley & Sons, Inc.

creation, on the order of millions of hectares, being proposed to help solve a major coastal pollution problem in the Gulf of Mexico (see Case Study 2). Restoration done for water quality improvement also has major advantages of also providing habitat restoration and flood mitigation in addition to water quality improvement. The Skjern River Restoration Project in Europe provides a major river/riparian wetland restoration project in a previously drained landscape in Denmark's largest watershed (Case Study 3), while a fourth example of a hydrologic restoration at a culturally significant location in the world that is well underway is the restoration of the Mesopotamian Marshlands of Iraq (Case Study 4).

Case Study 1 – Restoring the Florida Everglades

The restoration of the Florida Everglades, the largest wetland area in the US, actually involves several separate initiatives being carried out in the 4.6 million ha Kissimmee–Okeechobee–Everglades (KOE) region in the southern third of Florida (Figure 2). Overall, the Everglades restoration, as now planned by the US Army Corps of Engineers and the South Florida Water Management District, will cost over \$12 billion and will be carried out over the next 20 years or more. The basic plan involves restoring something closer to the original hydrology of the KOE region, by sending less of the water from the upper watershed to the Caloosahatchee River to the west and the St Lucie Canal to the east (see Figure 2, middle diagram) and directing more of the water to the Everglades itself south of Lake Okeechobee (see Figure 2, right). Specific problems in the Everglades have developed because of (1) excessive nutrient loading to Lake Okeechobee and to the Everglades itself, primarily from agricultural runoff, (2) loss and fragmentation of habitat caused by urban and agricultural development, (3) spread of *Typha* and other invasives and exotics to the Everglades, replacing native vegetation, and (4) hydrologic alteration due to an extensive canal and straightened rivers system built by the US Army Corps of

Engineers and others for flood protection and maintained by several water management districts.

One major restoration project in the KOE region that has received a lot of attention is the restoration of the Kissimmee River. As a result of the channelization of the river in the 1960s, a 166-km-long river was transformed into a 90-km-long, 100-m-wide canal, and the extent of wetlands along the river decreased by 65%. The restoration of the Kissimmee River is a major undertaking to reintroduce the sinuosity to the artificially straightened river. The river restoration work, expected to be completed in stages over the next several decades, will return some portion of lost wetland habitat to the riparian zone and will also provide sinks for nutrients that are otherwise causing increased eutrophication in downstream Lake Okeechobee.

Everglades restoration also involves halting the spread of high-nutrient cattail (*Typha domingensis*) through the low-nutrient sawgrass (*Cladium jamaicense*) communities that presently dominate the Everglades. Since the main causes of the spread of cattails are nutrients and especially phosphorus emanating from agricultural areas in the basin, 16,000 ha of created wetlands, called Stormwater Treatment Areas (STAs) have been created for phosphorus control from the agricultural area (Figure 3). A prototype of the STAs, a 1500 ha site, called the Everglades Nutrient Removal (ENR) project has operated since mid-1994 (Reddy *et al.*, 2006).

Case Study 2 – Creating and Restoring Wetlands to Solve the Gulf of Mexico Hypoxia

A hypoxic zone has developed off the shore of Louisiana in the Gulf of Mexico where hypolimnetic waters with dissolved oxygen less than $2 \text{ mg l}^{-1} \text{ O}_2$ now extend over an area of 1.6–2.0 million ha (Rabalais *et al.*, 2001). Nitrogen, particularly nitrate-nitrogen, is the most probable cause; 80% of the nitrogen input is from the 3 million km^2 Mississippi River basin. The basin represents 41% of lower 48 states of the USA.

Figure 3 Map of the location of 16,000 ha of Stormwater Treatment Areas (STAs) created north of the Florida Everglades to reduce phosphorus pollution from the Everglades Agricultural Area. Source: South Florida Water Management District, West Palm Beach, Florida.

The control of this hypoxia is important in the Gulf of Mexico because the continental shelf fishery in the Gulf is approximately 25% of the US total. A number of options were investigated for controlling nutrient flow into the Gulf (Mitsch *et al.*, 2001). In the end, there are three general approaches that involve either revision of agronomic approaches or wetland creation and riparian restoration that make the most sense (Figure 4). Two million ha of restored and created wetlands and restored riparian buffers have been

recommended as necessary to provide enough nitrogen retention to substantially reduce the nitrogen entering the Gulf of Mexico (Mitsch *et al.*, 2001; Mitsch and Day, 2006). That area is less than 1% of the Mississippi River Basin. Interestingly, Hey and Phillips (1995) found that a similar scale of wetland restoration would be required in the Upper Mississippi River Basin to mitigate the effects of very large and costly floods such as the one that occurred in the summer of 1993 in the Upper Mississippi River Basin.

Figure 4 Schematic of agricultural landscape in Mississippi River Basin with wetlands and riparian zones for controlling nitrogen pollution from agricultural fields. Reprinted from Mitsch WJ and Gosselink JG (2007) *Wetlands*, 4th edn., 582 pp. New York: John Wiley & Sons, Inc.

Case Study 3 – The Skjern River Restoration Project, Denmark

River restoration has flourished since the early 1990s in Denmark. The Skjern River in west central Jutland drains more than 11% of Jutland, and the flow of water in the Skjern is the largest in Denmark. In Denmark's largest drainage project ever, 4000 ha of wet meadow was converted into arable land, and the lower Skjern was straightened to a fraction of its former meandering self. By the late 1980s, the river was essentially a straight line to the Ringkøbing Fjord on the North Sea, eliminating thousands of hectares of marshland, meadows, and river habitat. The channelized river was diked, canals were built, and pumps were installed to hasten the downstream movement of water from the land. This public works project cost DDK 30 million (about US\$3.6 million) and was considered a success by the agricultural community at first as grains could now be grown in the formerly wet region. But the environment was paying a heavy price with this artificial river. The self-cleansing ability of the river was lessened, the downstream fjord was becoming polluted with nutrients and sediments, and the land that was draining began to subside due to peat oxidation and loss of water – up to 1 m or more in some locations. A few years after the drainage, it appeared that another drainage project might be necessary, but the Danish Parliament (Folketing) passed a Public Works Act in 1998 with a huge majority that called for the restoration of the lower Skjern River and earmarked about DDK 254 million for this project. The project is being implemented in three phases for three reaches of the river. Nineteen kilometers of the river and 2200 ha of the river valley wetlands were restored over 1998–2002 (Figure 5) by putting back the meanders of the river wherever possible, removing dikes along the river to allow adjacent meadows to once again be flooded, and moving the dikes far away from the river to prevent flooding of farmland outside of the project area. The project was

successful in substantially increasing the biodiversity of the region with aquatic macrophytes, invertebrates, amphibians, and mammals such as otters (Pedersen *et al.*, 2007).

Case Study 4 – Restoration of the Mesopotamian Marshlands

The Mesopotamian Marshlands of southern Iraq and Iran, found at the confluence of the historic Tigris and Euphrates Rivers, were 15,000–20,000 km² in area as recently as the early 1970s but were drained and diked, especially in the 1990s, to less than 10% of that extent by 2000. Among the main causes are upstream dams and drainage systems constructed in the 1980s and 1990s that altered the river flows and eliminated the flood pulses that sustained the wetlands. Since the overthrow of Saddam Hussein's dictatorship in 2003 in Iraq, there has been a concerted effort by the Iraqis and the international community at restoring the marshlands (Richardson *et al.*, 2005). The restoration has often occurred with local residents breaking dikes or removing impediments to flooding. Remote sensing images showed that at least 37% of the wetlands were restored by 2005, and *Frontiers in Ecology and the Environment* (Vol. 3, No. 8, October 2005) reported that year "at least 74 species of migratory waterfowl and many endemic birds have been sighted in a survey of Iraq's marshland... ." It was also reported that as many as 90,000 Marsh Arabs have returned to the wetlands already (Azzam Alwash, personal communication, 2006). Alwash, the Director of the Eden Again effort, has suggested that perhaps as much as 75% of the marshlands will be restored. There are still several questions that remain unanswered about whether full restoration can occur, including whether adequate water supplies exist given the competition from Turkey, Syria, and Iran, and within Iraq itself, and whether landscape connectivity of the marshes can be re-established (Richardson and Hussain, 2006).

Figure 5 Skjern River restoration area in western Denmark illustrating restoration and floodplain (meadow, lake, and swamp) restoration and river before restoration. Reproduced from Pedersen ML, Andersen JM, Nielsen K, and Linnemann M (2007) Restoration of the Skjern River and its valley: Project description and general ecological changes in the project area. *Ecological Engineering* 30: 131–144.

Peatland Restoration

Peatland restoration is a relatively new type of wetland restoration compared to other types and potentially could be the most difficult (Gorham and Rochefort, 2003). Early attempts with peatlands occurred in Europe, specifically in Finland, Germany, UK, and The Netherlands. Increased peat mining in Canada and elsewhere has led to increased interest in understanding if and how mined peatlands can be restored. When peat surface mines are abandoned without restoration, the area rarely returns through secondary succession to the original moss-dominated system (Quinty and Rochefort, 1997). There is promise that restoration can be successful but because (1) surface mining causes major changes in local hydrology and (2) peat accumulates at an exceedingly slow rate, restoration progress will be measured in decades rather than years. In the 1960s and 1970s, block harvesting of peat was replaced by vacuum harvesting in southern Quebec and in New Brunswick, necessitating the development of different restoration techniques. While traditional block-cutting of peat left a variable landscape of high ground and trenches, vacuum harvesting left relatively flat surfaces bordered by drainage ditches. Abandoned block-cut sites appear to revegetate with peatland species more easily than do vacuum-harvested sites, and the latter can remain bare for a decade or more after mining (Rochefort and Campeau, 1997).

Case Study 5 – Bois-des-Bel Peatland, Québec, Canada

Despite the vast expanses of peatlands in the world, whole-ecosystem experiments on this type of wetland are rare. Bois-des-Bel peatland, located about 200 km northeast of Québec City, on the southern shore of the St Lawrence River in Québec, Canada, is a whole-ecosystem research site where scientists are evaluating the pace of peatland restoration after peat mining (Rochefort et al., 2003). The entire peatland is about 210 ha; the research area is about 11.5 ha of peatland that was drained in 1972 and mined by a vacuum extraction

technique from 1973 to 1980. When mining stopped, a 2-m peat deposit remained. Restoration began in 1999 on 8.4 ha of the site, with the remaining as an unrestored control. The restored area was divided into four zones, each of which has two shallow pools (13 m × 5 m × 1.5 m max depth) for aquatic and amphibian habitat. Line Rochefort and her students and colleagues at Université Laval, Quebec City, and at other Canadian universities have established the site as a long-term ecosystem research site here to investigate the revegetation of mined peatlands (Price et al., 1998; Rochefort et al., 2003; Waddington et al., 2003, 2008; Isselin-Nondedeu et al., 2007). The restoration involved terracing to produce better water distribution, reintroduction of *Sphagnum* diaspores harvested from a nearby natural wetland, and reflooding by blocking drainage ditches. The moss carpet increased by about 12 cm by 2007 and was three times the thickness that it was in 2003. *Sphagnum* cover by 2005 was 60% of the area in the restored sites compared to only 0.25% in the nonrestored sites (Isselin-Nondedeu et al., 2007). The restored sites also exported less than half the dissolved organic carbon than did the cutover peatland sites (Waddington et al., 2008).

Coastal Wetland Restoration

There is a great deal of interest in coastal wetland restoration. Early pioneering work on salt marsh restoration was done in Europe, China, North Carolina, Chesapeake Bay and Delaware Bay in the USA, and along the coastlines of Florida, Puerto Rico, and California. Some of this coastal wetland restoration has been undertaken for habitat development as mitigation for coastal development projects. For coastal salt marshes in Eastern US, the cordgrass *Spartina alterniflora* is the primary choice for coastal marsh restoration; but the same species is considered an invasive and unwanted plant on the west coast of North America. Both *Spartina townsendii* and *S. anglica* have

been used to restore salt marshes in Europe and in China although both species are considered to be invasive by some in China and New Zealand. Salt marsh grasses tend to distribute easily through seed dispersal, and the spread of these grasses can be quite rapid once the reintroduction has begun, as long as the area being revegetated is intertidal, that is the elevation is between ordinary high tide and low tide.

Restoring mangrove swamps in tropical regions of the world has some similar characteristics to restoring salt marshes in that the establishment of vegetation in its proper intertidal zone is the key to success. But that is generally where the similarities end. Mangrove restoration is more cosmopolitan in that it has been attempted throughout the tropical and subtropical world (Lewis, 2005); salt marsh restoration has been attempted primarily on the Eastern North American and Chinese coastlines and to some extent in Europe and the west coast of North America. Salt marsh restoration can often rely on water-borne seeds distributing through an intertidal zone; mangrove restoration often involves the physical planting of trees. In countries such as Vietnam, mangrove declines have been attributed to the spraying of herbicides during the Vietnam war, and immigration of people to the coastal regions, leading to cutting of lumber for timber, fuel, wood, and charcoal.

Mangroves are being cleared for construction of aquaculture ponds at unprecedented rates in Vietnam and many other tropical coastlines of the world (Bentham *et al.*, 1999). Most of the edible shrimp sold in the US and Japan are produced in artificial ponds constructed in mangrove wetlands in Thailand, Indonesia, and Vietnam. These products are the result of massive destruction of mangrove forests and are sold in the US and Japan at very low prices. More than 100,000 ha of abandoned ponds located in former mangrove swamps currently exist in these countries (R. Lewis, personal communication). In Vietnam, mangroves are being restored and protected to provide coastal protection and coastal fisheries support. In the Philippines, despite a presidential proclamation in 1981 prohibiting the cutting of mangroves, it is estimated that the country was still losing 3000 ha yr⁻¹ in the late 1990s (2.4% yr⁻¹; de Leon and White, 1999). Shrimp ponds last only about 5–6 years before they develop toxic levels of sulfur and are then abandoned, and more mangroves are destroyed. These abandoned ponds present a challenge for mangrove restoration.

Several studies emphasized the importance of restoring tidal conditions, including salinity, to marsh or mangrove areas that had become more “freshwater” because of isolation from the sea. In cases such as this, the restoration is simple – remove whatever impediment is blocking tidal exchange. Case Study 6 describes a salt marsh restoration in Delaware Bay where that is exactly the case – restore the natural tidal hydrology, and the vegetation and aquatic species will follow.

Case Study 6 – Delaware Bay Salt Marsh Restoration

A large coastal wetland restoration project in Eastern USA involves the restoration, enhancement, and preservation of 5000 ha of coastal salt marshes on Delaware Bay in New Jersey

and Delaware in northeastern USA (Teal and Peterson, 2005). This estuary enhancement, being carried out by New Jersey's electric utility with advice from a team of scientists and consultants, was undertaken as mitigation for the potential impacts of once-through cooling from a nuclear power plant operated on the Bay. The reasoning was that the impact of once-through cooling on fin fish, through entrainment and impingement, could be offset by increased fisheries production from restored salt marshes. Because of uncertainties involved in this kind of ecological trading, the area of restoration was estimated as the salt marshes that would be necessary to compensate for the impacts of the power plant on fin fish times a safety factor of four. There are two distinct approaches being utilized in this project to restore the Delaware Bay salt marshes:

1. Reintroduce flooding: The most important type of restoration involves the reintroduction of tidal inundation to about 1800 ha of former diked salt hay farms. Many marshes along Delaware Bay have been isolated by dikes from the bay, sometimes for centuries, and put into the commercial production of “salt-hay” (*Spartina patens*). Hydrologic restoration was accomplished by excavating breaches in the dikes and, in most cases, connecting these new inlets to a system of recreated tidal creeks and existing canal systems. From a hydrodynamic perspective, in those marshes where tidal exchange was restored, the development of an intricate tidal creek density from the originally constructed tidal creeks has been impressive. The “order” of the stream channels increased from 5 or less to well over 20 from 1996 through 2004. The number of small tributaries increased from “dozens” to “hundreds” at all three salt hay farm sites that were reopened to tidal flushing. Hydrologic design did occur in “self-design” fashion after only initial cuts by construction of the first-order channels.
2. Reduce *Phragmites* domination: In another set of restoration sites in Delaware and New Jersey, restoration involves the reduction in cover of the aggressive and invasive *Phragmites australis* in 2100 ha of nonimpounded coastal wetlands. Alternatives that were investigated include hydrological modifications such as channel excavation, breaching remnant dikes, microtopographic changes, mowing, planting, and herbicide application.

Results of this study were reported in several early journal articles (e.g., Weinstein *et al.*, 1997, 2001; Teal and Weinstein, 2002) and more recently in a journal special issue of 10 papers related to this salt marsh restoration (Peterson *et al.*, 2005). For the salt hay farms that were flooded, typical goals include a high percent cover of desirable vegetation such as *Spartina alterniflora*, a relatively low percent of open water, and the absence of the invasive reed grass *Phragmites australis*. Reestablishment of *Spartina alterniflora* and other favorable vegetation has been rapid and extensive. Approximately 64% of one site was dominated by *Spartina alterniflora* after only two growing seasons and 87% by the fifth year after construction (Figure 6). Tidal restoration was completed at a larger site and major revegetation by *Spartina alterniflora* and some *Salicornia* already occurred with 71% of the site showing desirable vegetation after only four growing seasons. The study has

Figure 6 Restoration of Dennis Township salt marsh on Delaware Bay, New Jersey, USA, from initial conditions in 1995 to restored salt marsh in 2003. Reproduced from Hinkle R and Mitsch WJ (2005) Salt marsh vegetation recovery at salt hay farm wetland restoration sites on Delaware Bay. *Ecological Engineering* 25: 240–251.

shown that the speed with which restoration takes place is dependent on three main factors: the degree to which the tidal “circulatory system” works its way through the marsh; the size of the site being restored; and the initial presence of *Spartina* and other desirable species. No planting was necessary on these sites as *Spartina* seeds arrive by tidal fluxes; but the design of the sites to allow that tidal connectivity (and hence the importance of appropriate site elevations relative to tides) was critical. Self-design works when the proper conditions for propagule disbursement are provided.

River Delta Restoration

As large rivers connect to the sea, multitransitory deltas tend to develop, allowing the river to discharge to the sea in many channels. Many of these rich-soil deltas are among the most important ecological and economic regions of the world, from the ancient Nile delta in Egypt to the modern-day Mississippi River delta in Louisiana. There should be two major ecological resource goals of delta areas: (1) protecting and restoring the functioning of the deltaic ecosystems in the context of a geologically dynamic framework and (2) controlling pollution from entering the downstream lakes, oceans, gulfs, and bays. Delta restoration should have this dual emphasis where possible – ecosystem enhancement of the delta itself and improvement of coastal water-quality downstream. The best strategy for delta restoration when “land building” is a prerequisite (see Louisiana case study below) is to restore the ability of the river to “spread out its sediments” in deltaic form as wide an area as possible, particularly during flood events and by not discouraging (or encouraging and even creating) river distributaries. When river distributaries are not possible on a large scale due to navigation requirements or population locations, then restoring and creating riverine wetlands and constructing river diversions to divert river water to adjacent lands may be the best alternatives to maximize nutrient retention and sediment retention. In some cases, this involves the conversion of agricultural lands back to wetlands; in other cases, the dikes that “protect” wildlife protection ponds or retain rivers in their channels only need to be carefully breached to allow lateral flow of rivers during flood season.

Case Study 7 – Louisiana Delta Restoration

Louisiana is one of the most wetland-rich regions of the world with 36,000 km² of marshes, swamps, and shallow lakes. Yet Louisiana is suffering a rate of coastal wetland loss of 6600–10,000 ha yr⁻¹ as it converts to open water areas on the coastline, due to natural (land subsidence) and human causes such as river levee construction, oil and gas exploration, urban development, sediment diversion, and possibly climate change. There has been, since the early 1990s, a major interest in reversing this rate of loss and even gaining coastal areas, particularly freshwater marshes and salt marshes, the loss of which are the major symptom of this “land loss.” Clearly since the disaster in Louisiana and New Orleans caused by Hurricane Katrina in 2005, there is intense interest in restoring the Louisiana delta. But the enormous cost of reestablishing human settlements and putting back levees that were breached

during the hurricane has led some to doubt if there are enough resources to carry out the needed wetland restoration as well (Costanza *et al.*, 2006). Yet the wetlands are vital to the long-term survival of New Orleans. River diversions are becoming a large part of the delta restoration in Louisiana. The deltaic wetlands in Louisiana cover more than 20,000 km² and are critical to building land and wetlands from open water in the delta and may be critical nutrient removal sites for abatement of Gulf hypoxia (see Case Study 2 above). The Caernarvon freshwater diversion is one of the largest of several diversions currently in operation on the Mississippi River in Louisiana. The diversion structure is on the east bank of the river below New Orleans 131 km upstream of the Gulf of Mexico. The structure is a five-box culvert with vertical lift gates with a maximum flow of 226 m³ s⁻¹. Freshwater discharge began in August 1991 and discharge from then until December 1993 averaged 21 m³ s⁻¹; current minimum and maximum flows are 14 and 114 m³ s⁻¹, respectively, with summer flow rates generally near the minimum and winter flow rates 50–80% of the maximum (Lane *et al.*, 1999). The Caernarvon diversion delivers water to the Breton Sound estuary, a 1100 km² area of fresh, brackish, and saline wetlands.

Creating and Maintaining the Proper Hydrology

The key to restoring and creating wetlands is to develop appropriate hydrologic conditions. Groundwater inflow is often desired because this offers a more predictable and less seasonal water source. Surface flooding by rivers gives wetlands a seasonal pattern of flooding, but such wetlands can be dry for extended periods in flood-absent periods. Depending on surface, runoff and flow from low-ordered streams can be the least predictable. Often wetlands developed under these conditions are isolated pools and potential mosquito havens for a good part of the growing season; their design should be carefully considered. It is generally considered to be optimum to build wetlands where they used to be and where hydrology is still in place for the wetland to survive. But tile drainage, ditches, and river downcutting have often changed local hydrology from prior conditions. Most biologists have difficulty in estimating hydrologic conditions whereas engineers often overengineer control structures that need substantial maintenance and are not sustainable.

Soils

Often choice of the site of wetland creation and restoration is limited by property ownership. If a choice exists, a wetland that is restored on former wetland (hydric) soils is much preferred over one constructed on upland soils. Hydric soils develop certain color and chemical patterns because they have spent long periods flooded and thus under anaerobic conditions. The soil color is mostly black in mineral hydric soils because iron and manganese minerals have been converted to reduced soluble forms and have leached out of the soil. In most cases, developing wetlands on hydric soils has three advantages:

1. hydric soils indicate that site may still have or can be restored to appropriate hydrology;

2. hydric soils may be a *seedbank* of wetland plants still established in the soil; and
3. hydric soils may have the appropriate soil chemistry for enhancing certain wetland processes. For example, mineral hydric soils generally have higher soil carbon than do mineral nonhydric soils. This soil carbon, in turn, stimulates wetland processes such as denitrification and methane production.

Otherwise, it is possible to create wetlands on upland soils, and in the long run, these soils will develop characteristics typical of hydric soils such as higher carbon content and seed banks.

Natural Succession versus Horticulture

To develop a wetland that will ultimately be a low-maintenance one, natural successional processes need to be allowed to proceed. The best strategy is usually to introduce, by seeding and planting, as many native choices as possible to allow natural processes to sort out the species and communities in a timely fashion. Wetlands created or restored by this approach are called *self-design wetlands*. Providing some help to this selection process, for example, selective weeding, may be necessary in the beginning, but ultimately the system needs to survive with its own successional patterns unless significant labor-intensive management is possible. A somewhat different approach, called *designer wetlands*, occurs when specified plant species are introduced, and the success or failure of those plants are used as indicators of success or failure of that wetland. This is akin to horticulture.

An important general consideration of wetland design is whether plant material is going to be allowed to develop naturally from some initial seeding and planting or whether continuous horticultural selection for desired plants will be imposed. Odum (1987) suggested "in many freshwater wetland sites, it may be an expensive waste of time to plant species which are of high value to wildlife.... It may be wiser to simply accept the establishment of disturbance species as a cheaper although somewhat less attractive solution." Reinartz and Warne (1993) found that the way vegetation is established can affect the diversity and value of the mitigation wetland system. Their study showed that early introduction of a diversity of wetland plants may enhance the long-term diversity of vegetation in created wetlands. The study examined the natural colonization of plants in 11 created wetlands in southeastern Wisconsin. The wetlands under study were small, isolated, depressional wetlands. A 2-year sampling program was conducted for the created wetlands, aged 1–3 years. Colonization was compared to five seeded wetlands where 22 species were introduced. The diversity and richness of plants in the colonized wetlands increased with age, size, and proximity to the nearest wetland source. In the colonized sites, *Typha* spp. comprised 15% of the vegetation for 1-year wetlands, and 55% for 3-year wetlands, with the possibility of monocultures of *Typha* spp. developing over time in colonized wetlands. The seeded wetlands had a high species diversity and richness after two years. *Typha* cover in these sites was lower than in the colonized sites after 2 years.

Case Study 8 – To Plant or Not Plant Created Wetlands

A study where the effects of planting versus not planting have been observed for over 15 years is at two experimental wetlands at the Olentangy River Wetland Research Park in central Ohio (Figure 7; Mitsch *et al.*, 1998, 2005, 2012). In essence, both wetlands were different degrees of self-design since there were no expectations as to what the ultimate cover would be, and there was no "gardening" to get to any endpoint. After 3 years, both wetlands were principally dominated by soft-stem bulrush *Schoenoplectus tabernaemontani* (= *Scirpus validus*) and were thought to be similar. Researchers found that both planted and unplanted wetlands converged in most of the 16 ecological indicators (eight biological measures and eight biochemical measures) in those 3 years (Mitsch *et al.*, 1998). After 6 years, however, several communities of vegetation continued to exist in the planted basin, but a highly productive monoculture of *Typha* dominated the unplanted basin (Mitsch *et al.*, 2005).

This study has now completed over 15 years of observations where one full-scale wetland was planted, and an identical wetland remained unplanted. The wetlands showed that there are a few differences in wetland function that persist a decade planting in planted and unplanted (naturally colonizing) wetland basins that could be traced to effects of the initial planting (Mitsch *et al.*, 2012). Some values that we appreciate in wetlands, for example, carbon sequestration and amphibian production, were higher in the naturally colonizing wetland while other values such as macrophyte community diversity were higher in the planted wetland. Planting did have an effect, but whether to plant depends on the original objective of the wetland. If plant diversity is desired, then planting makes sense. If productivity and carbon sequestration are desired, it may be a waste of effort to plant unless there are no sources of plant propagules (seed banks or inflowing rivers, for example). In any regard, there appears to be a lingering long-term effect on ecosystem function caused by planting.

Estimating Success

There are few satisfactory methods available to determine the "success" of a created or restored wetland or even a mitigation wetland created to replace the functions lost with the original wetland (Mitsch and Wilson, 1996). It is clear from the many studies of created and restored wetlands that some cases are successes, while there are still far too many examples of failure of created and restored wetlands to meet expectations. In some cases, expectations were unreasonable, as when endangered species habitat was to be established in a heavily urbanized environment (Malakoff, 1998). In such cases, the original wetland should not have been lost to begin with. Where expectations are ecologically reasonable, there is optimism that wetlands can be created and restored and that wetland function can be replaced. The spotty record to date is due to three factors:

1. little understanding of wetland function by those constructing the wetlands;
2. insufficient time for the wetlands to develop; and
3. a lack of recognition or underestimation of the self-design capacity of nature.

Figure 7 Experimental and other created and restored wetlands at the Olentangy River Wetland Research Park, Columbus, Ohio.

Understanding wetlands enough to be able to create and restore them requires substantial training in plants, soils, wildlife, hydrology, water quality, and engineering. Replacement projects and other restorations involving freshwater marshes need enough time, closer to 15 or 20 years than to 5 years, before success is apparent. Restoration and creation of forested wetlands, coastal wetlands, or peatlands may require even more time. Peatland restoration could take decades or more. And, of course, forested wetland restoration generally takes a lifetime.

Principles for Proper Ecological Engineering of Wetlands

Some general principles of ecological engineering that apply to the creation and restoration of wetlands are outlined below (Mitsch and Jørgensen, 2004):

1. Design the system for minimum maintenance and a general reliance on self-design.
2. Design a system that utilizes natural energies, such as the potential energy of streams as natural subsidies to the system.
3. Design the system with the hydrologic and ecological landscape and climate.
4. Design the system to fulfill multiple goals but identify at least one major objective and several secondary objectives.
5. Give the system time.
6. Design the system for function, not form.
7. Do not overengineer wetland design with rectangular basins, rigid structures and channels, and regular morphology.

Zedler (2000a) had suggested the following additional ecological principles that should be applied to wetland restoration:

1. Landscape context and position are crucial to wetland restoration. See #3 design principle above. Wetlands are always a function of the watershed and ecological setting in which they are placed.
2. Natural habitat types are the appropriate reference systems. This suggests that while we may know how to build ponds, for example, are those the natural habitats of the area, even if they do increase waterfowl?
3. The specific hydrologic regime is crucial to restoring biodiversity and function. See # 2 and 3 design principles. In many cases, such as the Florida Everglades, the restoration is being done in the face of a massive change in the hydrologic character of the landscape.
4. Ecosystem attributes develop at different paces. Give the system time; see # 5 above. Hydrology develops quickly, vegetation over several years, and soils over decades. Yet we are quick to review and criticize created and restored wetlands after a couple of years.
5. Nutrient supply rates affect biodiversity recovery. There are low-nutrient and high-nutrient wetland systems. Low-nutrient wetlands are often more difficult to create or restore. High-nutrient inflows cause wetlands to go for power instead of biodiversity. In other cases, insufficient nutrients were the cause of wetland failure as was

the case in southern California salt marshes (Zedler, 2000b).

6. Specific disturbance regimes can increase species richness. This can clearly be the case if we allow the word "disturbance" to include flood pulses, fire, and even tropical storms.
7. Seed banks and dispersal can limit recovery of plant species richness. This is why restoring wetlands with seed banks can be so important. Another solution is to have a hydrologically or biologically "open" system with a multitude of inputs of propagules (plants, animals, and microbes) more likely.
8. Environmental conditions and life history traits must be considered when restoring biodiversity. See our discussion on self-design versus designer wetlands below.
9. Predicting wetland restoration begins with succession theory. Again, design principle # 5 says we need to give the system time. Ecological succession cannot be accelerated without other consequences. This also supports our contention that one must understand wetland science first before attempting to create and restore wetlands.
10. Genotypes influence ecosystem structure and function. This is an important but often overlooked principle of wetland restoration. Species are not the same everywhere. This has been shown in common garden experiments on *Spartina alterniflora* (Seliskar, 1995) and freshwater rush *Juncus effusus* (Weihe and Mitsch, 2000). A brackish/freshwater wetland plant with this several genotypes that has invaded many natural and restored wetlands in the USA is *Phragmites australis*. This creates a difficult problem in wetland creation and restoration as wetland managers must be able to distinguish between the invasive "bad" *Phragmites* and the native "good" *Phragmites*.

Robin Lewis and Kevin Erwin, two wetland consultants from Florida, have spent about five decades restoring and creating wetlands around the world. Their experience has led to the following 15 recommendations (Lewis *et al.*, 1995):

1. Wetland restoration and creation proposals must be viewed with great care, particularly when promises are made to restore or re-create a natural system in exchange for a permit.
2. Multidisciplinary expertise in planning and careful project supervision at all project levels is needed.
3. Clear, site-specific measurable goals should be established.
4. A relatively detailed plan concerning all phases of the project should be prepared in advance to help evaluate the probability of success.
5. Site-specific studies should be carried out in the original system prior to wetland alteration if wetlands are being lost in the project.
6. Careful attention to wetland hydrology is needed in design.
7. Wetlands should, in general, be designed to be self-sustaining systems and persistent features of the landscape.
8. Wetland design should consider relationships of the wetland to the watershed, water sources, other wetlands in the watershed, and adjacent upland and deepwater habitat.

9. Buffers, barriers, and other protective measures are often needed.
10. Restoration should be favored over creation.
11. The capability for monitoring and mid-course corrections is needed.
12. The capability for long-term management is needed for some types of systems.
13. Risks inherent in restoration and creation and the probability of success for restoring or creating particular wetland types and functions should be reflected in standards and criteria for projects and project design.
14. Restoration for artificial or already altered systems requires special treatment.
15. Emphasis on ecological restoration of watersheds and landscape ecosystem management requires advanced planning.

The above principles and practices of wetland creation and restoration are based on wetland science (hydrology, biogeochemistry, adaptations, and succession). If one is interested in creating and restoring wetlands, one should first become an expert in wetland science. When we attempt to create or recreate natural ecosystems, Mother Nature is in control. In all situations of wetland creation and restoration, human contribution to the design of wetlands should be kept simple and should strive to stay within the bounds established by the natural landscape. As stated by Boulé (1988) "simple systems tend to be self-regulating and self-maintaining." We should recognize that Nature remains the chief agent of self-design, ecosystem development, and ecosystem maintenance; humans are not the only participants in these processes. We have referred to these self-design and time requirements for successful ecosystem restoration and creation as invoking "Mother Nature and Father Time" (Mitsch and Wilson, 1996; Mitsch *et al.*, 1998, 2012).

Glossary

Biodiversity Variety of living genotypes, populations, species, communities, and landscapes; for the case of species it includes the number of different species, their relative abundance, differences in their composition or functional attributes, their spatial patterns, and the complexity of their trophic interactions.

Ecosystem process Transfers of energy and materials given by interactions among abiotic (nonliving) and biotic (living) components of ecosystems.

Ecosystem resilience Ability of an ecosystem to maintain its functioning in the face of changing environmental conditions and disturbances.

Ecosystem service Ecosystem component or process that directly contributes to human well-being as it is consumed,

experienced, or it regulates the environmental conditions in which humans live.

Ecosystem service provider Components of populations, communities, trophic groups, landscapes, and habitats that are necessary for the delivery of ecosystem services.

Human well-being People's condition and capacities allowing secure access to food, water, energy, and shelter of adequate quality to meet their needs, and ensure good health as well as social connections.

Meta-analysis Statistical synthesis of the results of separate studies (quantitative research synthesis).

Spatial and temporal scale Spatial or temporal extent within which biodiversity interacts with ecosystem processes, ecosystem processes operate, and ecosystem services are delivered.

Why Worry About the Links Between Biodiversity and Ecosystem Services?

We are increasingly concerned about the impacts of human enterprise on biodiversity and ecosystem functioning, and their ability to continue to deliver the ecosystem services that are essential for human life. To meet humanity's rapidly increasing demand for fuel, water and food, human impacts on ecosystem have also been increasing, accumulating and interacting, leading to irreversible changes in the way ecosystems function. Anthropogenic climate change caused by an increase in the atmospheric concentration of greenhouse gases, large additions of nitrogen and phosphorus activated by humans to soil, water and atmosphere resulting from modern agriculture, and rates of biodiversity loss have all crossed boundaries for sustainable functioning of the Earth system (Rockstrom *et al.*, 2009).

Species are lost today at rates 10–100 times higher than those found in the fossil record. Predictions for extinction rates in the twenty-first century are up to 100 times higher than those found today (Millennium Ecosystem Assessment, 2005; Rockstrom *et al.*, 2009).

Given that ecosystem processes depend on living organisms, and that ecosystem functioning is given by the combination of such ecosystem processes, a key question to be answered is how will biodiversity loss impact the ability of ecosystems to continue meeting human needs.

The concept of ecosystem services was developed to show explicitly the tight connections between human well-being and the adequate provision of ecosystem services. The drive to satisfy human needs is threatening the maintenance of ecosystem functioning, while at the same time human impacts on ecosystems threaten their continued ability to satisfy human needs.

Introduction to the Concepts

New concepts have been coined in the past few years to advance key frontiers of knowledge, and old ones have been used in different contexts to address the multifaceted nature of the relationship between biodiversity and ecosystem services.

Biodiversity

Biodiversity is a term used to encompass all the variability found in living organisms in terrestrial and aquatic systems. This variability can be observed at different levels of organization. The variability among genomes of individuals, among populations of individuals within the same species, among species within a community, or among communities within a landscape can all be analyzed and may be linked to ecosystem services (Diaz *et al.*, 2006). Various mechanisms can generate biodiversity effects on ecosystem functioning. Species can be complementary in the way they contribute to the function and thus higher species richness leads to higher magnitude of the function. Sampling (or selection) effect is given by the increasing probability of including a highly efficient species for a particular function with increasing species richness increasing the probability of choosing this species as a result of random sampling. These two mechanisms are the most frequently called for; in fact, the most common is the combination of both. Facilitation occurs when a given species has a positive effect on the functional contribution of another one. To date, despite the accepted importance of these mechanisms, actual tests of their operation are much less frequent (Cardinale *et al.*, 2011).

The simplest and more direct way to analyze the variability is through the counting of the number of different types of

units, otherwise called richness. The most common use of this term is in reference to species richness, the number of species found in a community. The relative abundance of species is also a part of this variability, given that an ecosystem largely dominated by a single species will function in a different way than one with the same richness but with even abundance of species. Differences in species composition, not only in terms of their taxonomic identity, but also in terms of the differences in the way they respond to environmental conditions and contribute to ecosystem functions, will lead to changes in ecosystem services. The variability in morphological or functional attributes of species is called functional diversity. The distribution patterns of species in space are also relevant to ecosystem functioning, and species can either be evenly distributed across space or rather clumped into patches of different sizes. The structure of a food web, in terms of the number of trophic levels and the number of linkages between species is also relevant to ecosystem functioning and has been referred to as vertical diversity.

A rich literature has developed exploring the links between biodiversity and ecosystem services in many ways. Such a wealth of data and theory has led to syntheses on the role of species richness in ecosystem functioning and provision of ecosystem services that will be discussed below. A large fraction of the explorations of the links between biodiversity and ecosystem services focus on species richness (Figure 1). Yet, the roles of species composition or identity, functional diversity, species' relative abundance, species' spatial distribution patterns, and trophic diversity are increasingly being recognized and investigated (Table 1); the same is true for the roles of genetic diversity in ecosystem functioning and ecosystem services. To date there is a very large amount of evidence available that indicates that increased producer species richness increases the efficiency by which plants and algae convert

these into standing biomass; this is true for temperate grasslands, agricultural systems, marine coastal systems and lakes (Cardinale *et al.*, 2011).

Ecosystem Processes and Ecosystem Functioning

Ecosystem processes are the interactions among abiotic or nonliving and biotic or living components of terrestrial and aquatic ecosystems. Such interactions encompass transfers of energy and materials (Chapin *et al.*, 2000).

One of the central processes in terrestrial and aquatic ecosystems is the transformation of solar energy into biomass through photosynthesis. Primary productivity, the change in primary producer biomass per unit area and time, is the result of photosynthesis, respiration, and decomposition leading to net plant growth. Numerous studies have explored the links between biodiversity and some components of this process, largely as total biomass of primary producers or the rates at which this accumulates. To date there is a very large amount of evidence available that indicates that increased producer species richness increases the efficiency by which plants and algae convert these into standing biomass; this is true for temperate grasslands, agricultural systems, marine coastal systems and lakes (Cardinale *et al.*, 2011).

The biomass stored in primary producers is either consumed or decomposed. The effects of biodiversity have been frequently studied for secondary production (consumption) or decomposition. Such studies have measured biomass consumed or decomposed, amounts of carbon liberated to the atmosphere, as well as respiration rates to assess the activity of decomposers.

The cycling of several key elements – phosphorus, nitrogen, sulfur and carbon – can also be linked to biodiversity. The loss of species of primary producers, particularly plants in

Figure 1 Components and levels of organization of biodiversity that have been related to ecosystem services. Results are derived from a search in ISI Web of Science and Biological Abstracts in May 2011 for all past references using the term in the graph and “(plant or invertebrates or nonvascular plants or microbes or aquatic plants or vertebrates) and ecosystem services”.

Table 1 Selected examples of ecosystem services and their ecosystem service providers. Characteristics of the providers refer to the level of organization or the components of diversity involved in service delivery

<i>Ecosystem service provider</i>	<i>Characteristics of the providers</i>	<i>Processes</i>	<i>Service</i>	<i>Type of ecosystem service</i>	<i>Spatial scale</i>	<i>References</i>

Vegetation	Populations, species, communities, ecosystems	Primary production	Agricultural food production	Provisioning	Local to landscape	Jackson <i>et al.</i> (2009)
Leaf litter and soil invertebrates, soil microorganisms, nitrogen-fixing plants, plant and animal production of waste products	Populations, species, functional groups	Decomposition, Nutrient cycling	Regulation of soil productive potential	Regulating	Local	van der Heijden <i>et al.</i> (1998) and Barrios (2007)
Insects, birds, mammals	Populations, species, functional groups	Trophic interactions, Movement of pollen and seeds by animals	Pollination	Regulating	Local to landscape	Kremen <i>et al.</i> (2007) and Klein <i>et al.</i> (2009)
Microorganisms, invertebrate parasitoids, vertebrate predators	Populations, species, functional groups	Trophic interaction	Regulation of human disease vectors	Regulating	Local to global	Jones <i>et al.</i> (2008) and Keesing <i>et al.</i> (2010)
Many types of organisms	Populations, species, communities, ecosystems	Ecological–social dynamics	Aesthetic and spiritual inspiration, sense of identity	Cultural	Local to global	Chan <i>et al.</i> (2011)

temperate grasslands, has been shown to reduce the efficiency by which they assimilate inorganic resources such as soil nitrate (Cardinale *et al.*, 2011). Yet, the information available to date does not allow generalizing these findings to other elements or to other ecosystems. This is particularly worrying given that the concentrations and cycles of these elements have been substantially altered by human activities over the past two centuries, strongly modifying the functioning of ecosystems and their ability to deliver ecosystem services (Millennium Ecosystem Assessment, 2005; Rockstrom *et al.*, 2009).

We know little about the role of biodiversity in the different components of the water cycle. Plant diversity, in the form of functional and structural diversity may play a key role in evapotranspiration, surface and underground runoff (Chapin *et al.*, 2002; Diaz *et al.*, 2006). The diversity of soil organisms (such as earthworms, micro-arthropods, and microbes) is related to soil physical properties such as the presence of macropores to aid infiltration (Barrios, 2007). Yet, not enough experimental nor observational data is consistently available to confirm the role of biodiversity on these processes.

Ecosystem functioning encompasses many of the above-mentioned processes and the interactions among them. Functioning includes the ability of the ecosystem to cope with natural and anthropogenic disturbance by converging around a particular state rather than changing dramatically into a very different condition for the components and processes that make them up. The latter is called ecosystem resilience.

The potential links between biodiversity and multiple ecosystem processes or ecosystem functioning are often referred to in scientific literature. Yet, only a fraction of such references correspond to actual data on such links.

Ecosystem Services

Ecosystem services are the links between ecosystems and human societies. In the broadest sense they are the benefits societies obtain from ecosystems (Millennium Ecosystem Assessment, 2005). More specifically, services are produced by living or nonliving components of ecosystems, through the conditions and processes in ecosystems. They contribute to human well-being in different ways: Services can be directly consumed, as in the case of water or food. Services can be experienced, as in the case of the scenic beauty or the sense of awe that a waterfall, a mountain covered by vegetation or a monarch butterfly can instill in us. Services also contribute to the fundamental environmental conditions for human life, such as the regulation of relatively stable climatic conditions and protection against extreme events.

Ecosystem services have also been defined as those components and processes of ecosystems that contribute directly to human well-being (Luck *et al.*, 2009). By emphasizing the direct nature of such connections an effort is being made to distinguish ecosystem processes from ecosystem services.

There is a fine line between ecosystem processes and ecosystem services. Some authors have considered ecosystem processes as those ecosystem services that support the delivery of all other types of services. The advantage of this position is that it is possible to encompass both direct benefits to human

societies as well as ecosystem functions and the origin and maintenance of biodiversity within the term ecosystem services. This approach can be very useful when communicating with decision makers.

Yet, in order to quantify the amount of services, a clear distinction between supply, service and value can be useful. Supply is the contribution of ecosystem processes and components to a service that can potentially benefit societies. Service is the actual benefit societies obtain from the service, which can include water consumption or the number of people that benefit from regulation of flooding. Value reflects how societies consider the relative importance of a service; it can be monetary, as an expression of markets or preferences or embedded into cultural perspectives (Chan *et al.*, 2011). In this section we will dissect ecosystem processes from ecosystem services in this way.

The key message is that services or benefits to human societies depend on ecosystems and their functioning. In turn, such functioning is dependent to some degree on biodiversity.

The Millennium Ecosystem Assessment (2005) classifies services into four types: supporting, provisioning, regulating, and cultural services. The authors do not include supporting services, as they consider them to be ecosystem processes that indirectly benefit societies by supporting one of the other three types of services.

Provisioning Services

Provisioning services are the tangible resources or goods that people obtain from ecosystems. These are finite, can be renewable, and can be directly consumed, appropriated, and traded.

Food provision is among the most important services. Food can be obtained from agricultural activities, aquaculture, hunting, gathering, and fisheries. Other key provisioning services include fodder, wood, fibers, biofuels, and a diversity of abiotic and biotic resources derived from terrestrial and aquatic systems.

Regulating Services

Regulating services result from the contribution of multiple ecosystem processes to ecosystem functioning, specifically to the regulation of the conditions where humans live and make a living. Such regulation determines both the average and the variance in such conditions.

Regulating services include the regulation of local or global climate, of disease vectors and incidence, of pests, crop pollination, soil fertility, and soil erosion. They also regulate the amount, temporality, and quality of water provision, as well as the impact of severe weather conditions on ecosystems and people.

Cultural Services

Cultural services are ecosystems' contribution to the non-material benefits that arise from the interaction between people and ecosystems. These benefits include a range of capabilities and experiences (Chan *et al.*, 2011).

Cultural ecosystem services include the sense of place or identity linked to a particular ecosystem and its management. They also include activities such as recreation and work. The existence and bequest value of a site or a species for future

generations, or the sense of awe and spiritual or esthetic inspiration are also considered cultural services.

Ecosystem Service Provider

An ecosystem service provider is a biotic component of an ecosystem that is necessary for the delivery of an ecosystem service. Ecosystem providers can include populations, communities, trophic groups, landscapes, and habitats (Kremen, 2005; Luck *et al.*, 2009).

The concept of the ecosystem service provider was developed to identify the component(s) of the ecosystem that should be managed in order to ensure the sustained delivery of each service. Vascular and nonvascular plants, terrestrial and aquatic invertebrates, microbes, and vertebrates have been explicitly recognized as ecosystem service providers (see Table 1). Genetic diversity, species diversity, species richness, functional diversity, and vertical diversity have also been identified as such.

Human Well-Being

Human well-being is a complex concept that is not universal but rather context dependent. The different components of such well-being as well as their relative importance depend on the cultural, geographic, and historic development of societies.

The Millennium Ecosystem Assessment (Millennium Ecosystem Assessment, 2005) identified food, water and other materials, security, good health, and good social relations as the key components of well-being. A recent report by another interdisciplinary international team (Stiglitz *et al.*, 2010) emphasizes the need to simultaneously consider the following dimensions: material living standards (income, consumption, and wealth), health, education, personal activities including work, political voice and governance, social connections and relationships, environment (present and future conditions), and insecurity (of an economic as well as physical nature). To assess them both people's objective conditions and capabilities should be taken into account.

Human well-being is directly linked to the biodiversity that surrounds the many rural communities of the world, from which they obtain food, medicine, materials, and inspiration. The role that biodiversity plays in ecosystem processes, the services they provide and thus human well-being will be discussed below.

The Shape of the Relationship Between Species Diversity and Ecosystem Functions and Services

The shape of the relationship between the species diversity and the magnitude of ecosystem function or service is quite relevant for management. If the shape is asymptotic this means that losing the few first species may have little effect on the function, but the magnitude of the impacts of losing further species can increase in non-linear ways leading to a dramatic decline in the function or service once enough species have been lost (Figure 2). Experimental studies much more frequently find such a pattern, rather than a linear

Figure 2 Possible ecological consequences of diversity loss. (1) The redundancy response predicts that initial losses of diversity will be accompanied by minimal change in the ecosystem process because some fraction of species are redundant for that process; however, at some point, loss of species leads to rapid declines in ecological function. (2) Ecosystem function declines proportionally to species loss. (3) An abrupt loss in ecosystem functioning is given by the loss of a keystone species or last member of a key functional group, or the addition of a new species trait. (4) Even minimal species loss leads to an immediate catastrophe and large declines in the functioning of ecosystems. A thicker line for the redundancy model indicates that it is the most frequently found pattern (modified from Letourneau DK, Armbrrecht I, Rivera BS, *et al.* (2011) Does plant diversity benefit agroecosystems? A synthetic review. *Ecological Applications* 21: 9–21).

relationship, or one where losing the first few species has the most dramatic effects (Cardinale *et al.*, 2011). Similarly, observational studies have also found such an asymptotic pattern (Balvanera *et al.*, 2005). This means that losing species in already depauperate systems can have dramatic consequences for ecosystem functioning and ecosystem services.

Spatial and Temporal Scales

Spatial or temporal scale refers to the extent of the area or the duration of time. A related but different issue is the resolution, or grain, that refers to the smallest detectable event or property at a particular scale. Given that distribution patterns of biodiversity vary at different spatial and temporal scales, given that ecosystem processes operate at different scales, and given that services are delivered at different scales it is essential to clearly define the scale of analysis.

Spatial and temporal scales are continuous and dissected in a variety of ways, but for analytical purposes the authors have arbitrarily defined three contrasting scales here. The local spatial scale was defined here for areas up to 1 ha. This scale encompasses the area used for many of the local biodiversity assessments in terrestrial habitats (e.g., 0.1 ha assessment, or 1 ha assessment). Also, the experimental manipulations of biodiversity have used experimental units within this area range; for the case of those involving primary producers

(the most frequent ones) the median size of the experimental unit is 0.003 ha, and the largest ones have an area of 0.5 ha.

The landscape scale was defined as that ranging from 1 to 1000 ha. This range encompasses the area included into an individual piece of land to the whole area one can see from an elevated point under low to a very high visibility. This area encompasses well-known gradients in environmental conditions, a combination of individual lots of lands with natural, seminatural and anthropogenic conditions (e.g., agriculture and agroforestry), and can include one or various rural settlements. The regional scale to global scale was defined as that which includes 1000 ha and more. This range of areas can include a few rural settlements, one or many municipalities or urban settlements, all the way to whole states and countries. At this spatial scale use of remotely sensed data or spatially explicit models are needed to assess biodiversity distribution patterns as well as the magnitude of ecosystem processes and services.

The Complex Linkages between Biodiversity and Ecosystem Services: Selected Examples

What would happen if we lost most of the biodiversity? Would the delivery of ecosystem services be dramatically impaired? Do all ecosystem services show the same sensitivity to the loss of biodiversity? How universal is the asymptotic relationship between biodiversity and service provision?

All these are very complex and profound questions that have not been addressed thoroughly and systematically for all ecosystem services and at all spatial scales. The authors focus below on four very important and intensively studied ecosystem services. The authors show that they all depend on biodiversity, though in very different ways. The authors also show how they have been analyzed in very different ways.

Agricultural Food Production

Food production derived from agriculture depends on a wide diversity of crop species found across the planet. As many as 100 different crops used for human food are registered in global agricultural databases, and many more are locally grown and consumed. Yet, 63% of food production (as measured on a dry biomass basis) relies on only five species: sugar cane, maize, wheat, rice and potatoes (FAO, 2011).

Understanding the complex links between food production derived from agriculture and biodiversity is as relevant as ever, as feeding an expected nine billion people poses a paramount challenge. Most food production today is derived from highly intensive agricultural systems with low diversity. In fact, the sites with the highest agricultural yields (e.g., sites in China with 1.3 metric tons per hectare by year (MT); (FAO, 2011)) are those where most plants correspond to only one species and to one or a few genetic combinations (e.g., wheat and rice with 0.32 MT in China or sugar cane with 0.78 MT in Brazil; (FAO, 2011)). Also, the expansion and intensification of agricultural systems are the major driver of biodiversity loss of terrestrial habitats. On the other hand, the ability of diverse cropping systems, diverse agricultural landscapes, and

biodiversity friendly agricultural systems (e.g., organic) to meet global food needs is being debated.

The diversity of plant crops, as well as that of soil microorganisms and vertebrates, weeds, herbivores, and carnivores that interact with them is all relevant to the provision of this service. Also, diversity at different trophic levels, ranging from genetic diversity within populations to the diversity of communities within landscapes is relevant.

Agrobiodiversity, that is the variety and variability of living organisms that contribute to food and agriculture as well as the knowledge associated with them, can enhance agricultural food production. A recent meta-analysis of 552 experiments (Letourneau *et al.*, 2011) showed a general trend for positive effects of biodiversity. Diverse cropping schemes (polycultures) have been shown to have a significantly lower abundance of pests (herbivores), higher abundance of natural enemies of such pests (predators and parasites), decreased damage by pests, though at the cost of a small but significant reduction in crop yield (Figure 3).

Genetic diversity within populations, population diversity within crop species and community diversity within agricultural landscapes contribute to food production derived from agriculture. Farmers, particularly in developing countries, use a wide variety of traditional crop local varieties, or landraces, that still dominate production in many rural landscapes. Genetic and population diversity confers resilience in the face of abiotic (e.g., drought) and biotic (e.g., pests) stress, leading to more stable yields and higher adaptation to stressful conditions; various study cases support this well, though a systematic broader assessment is still needed to test the generality of such statements. Also, diversity of communities within agricultural landscapes, including low to high diversity agroecosystems and a mosaic of well-connected successional (recovering after agricultural use) and conserved patches of habitat provide increased resilience (Jackson *et al.*, 2009).

Regulation of Soil Productive Potential

Soils provide physical support, as well as water and nutrients needed for plants to grow, all of which can be encompassed into the regulation of soil productive potential. Services such as food production from agricultural systems, firewood, timber and biofuel production, and indirectly the regulation of soil erosion depend on the adequate regulation of soil conditions.

A tight but much more complex and less understood link exists between biodiversity and soil productive potential. The maintenance of the function of a large array of different types of organisms within soils is critical for maintaining agricultural, pastoral and forestry yield over the long term. Managing for increasing short term yield, such as the addition of inorganic fertilizers, may jeopardize the long term maintenance of biodiversity and this service. Yet, management is complex as it can hardly be targeted at specific groups or functions that we understand little.

Many different types of organisms (Table 2) participate in the regulation of soil productive potential (Barrios, 2007). Plants establish symbiotic associations with microorganisms that enhance the availability of otherwise limiting nutrients;

Figure 3 Effects of increased diversity associated to more diverse cropping schemes (polycultures) relative to less diverse ones or crop monocultures on various ecosystem services. The mean of the proportional effects of diversity and the 95% confidence intervals values derived from the meta-analysis are shown for each response variable. Significant effects correspond to average and confidence interval values that do not overlap with the no-effect line. Numbers above each result indicate the number of independent measurements found in the literature used for the analyses (modified from Winfree R, Aguilar R, Vazquez DP, LeBuhn G, and Aizen MA (2009) A metaanalysis of bees' responses to anthropogenic disturbance. *Ecology* 90: 2068–2076).

Table 2 Soil organisms and key functional groups of soil biota, soil processes they influence and ecosystem services they provide

Soil organisms	Key functional groups	Selected soil processes	Selected ecosystem services	Service classification
N-fixing organisms, mycorrhiza	Microsymbionts	Microsymbiosis	Nutrient uptake	Supporting
Cellulose and lignin degraders	Decomposers	Decomposition	Nutrient cycling	Supporting
Nitrifiers, denitrifiers	Elemental transformers	Elemental transformation	Nutrient cycling	Supporting
Earthworms, termites	Ecosystem engineers	Soil structure modification	Regulation of soil erosion, C sequestration, water flow and storage	Regulating
White grubs, plant-parasitic nematodes, root-rots	Soil-borne pest and disease	Herbivory, parasitism	Biological control of pests and disease	Regulating
Grazers	Microregulators	Grazing of decomposers	Nutrient cycling	Supporting

Source: Modified from Barrios E (2007) Soil biota, ecosystem services and land productivity. *Ecological Economics* 64: 269–285.

soil bacteria (e.g., *Rhizobium*) in symbiosis with leguminous plants fix atmospheric nitrogen into the soil, whereas soil-borne fungi in symbiosis with roots of many vascular plants, particularly the so-called arbuscular mycorrhizal fungi enhance phosphorus acquisition through the branching filamentous structure of fungi (hyphae). Decomposition of organic materials into simpler molecules is given by small invertebrates that break down dead tissues; by bacteria, fungi, protozoa, and invertebrates that chemically degrade dead organic matter further with enzymes; and by microorganisms that generate soluble and volatile organic and inorganic compounds. Earthworms, ants, and termites modify soil

structure by removing soil and creating structures by their activity; root-rots, plant-parasitic nematodes, and scarab beetle larvae are responsible for soil-borne diseases, whereas soil grazer, predators, or parasites drive the local food web (Table 2).

Richness of various types of organisms is linked to some of the processes related to the regulation of soil productive potential. Recent meta-analyses (Balvanera *et al.*, 2006; Hoeksema *et al.*, 2010; Quijas *et al.*, 2010) have shown that higher plant species richness contributes to significantly higher plant root biomass and decomposer activity, higher mycorrhizal richness leads to higher plant nutrient

concentration, and higher decomposer richness to higher decomposer activity. Instead, higher plant species richness contributes to lower decomposer biomass and soil nutrient supply.

Species composition and particularly functional composition and diversity are expected to have a paramount importance for the regulation of soil productive potential given the wide range of organism involved in the different processes. Growth form composition (e.g., legume and hemiparasitic plants) and growth form diversity (e.g., life form, root depth, photosynthetic capacity, and nitrogen-fixing capacity) contribute to higher nutrient uptake through increased functional diversity (de Bello *et al.*, 2010).

The links between biodiversity and the regulation of soil productive potential occur at local scales (Barrios, 2007). Soils are highly heterogeneous in terms of their physical, chemical, and microclimatic characteristics, as well as in terms of the spatial (horizontal and vertical) distribution of the soil biota, at scales ranging from microns to meters. Soil biota is concentrated in hot-spots of activity that are mostly associated with the availability of carbon substrates and water availability.

A better understanding of the spatial distribution patterns of soil biota at a wide range of spatial scales and the consequent impacts on soil processes is needed to allow for managing soils and maintaining the range of ecosystem services they provide.

Pollination

Mobile organisms pollinate many important crops and other plant species of commercial and social importance. In the absence of the native organisms that have contributed to this service, domestic European bees (*Apis mellifera*) have been introduced; in a few cases, pollination has been performed by hand by humans.

Pollination, a regulation service, provides benefits to human populations by increasing the production of those commercial and subsistence crops, fiber, fodder, wood, and non-timber forest products that require a mobile organism to transport male pollen grains into feminine floral structures for seed production. Pollination is also a supporting service, or ecosystem process, that enables the reproduction of many wild plants.

Pollination is important for 35% of the global crop production. Between 60% and 90% of wild plants (depending on the type of biome) require pollination; a larger proportion of the species benefit from flower visitation by mobile organisms.

Mobile organisms that visit flowers provide pollination services at the local scale at which such interaction occurs. Yet, these organisms move freely within and among habitats, and thus their individual, population, and community dynamics depend on the spatial distribution of resources at landscape or larger spatial scales (Kremen *et al.*, 2007).

Pollination is provided by wild animals. Bees are the most important pollinators. Yet, butterflies, moths, flies, beetles, wasps, birds, bats, and other invertebrates, and mammals are important for this service. Commercially managed bees are very important for the provision of the service in agricultural contexts; *Apis mellifera* is the most important pollination service provider globally to farmers.

Rich pollinator assemblages enhance pollination in different ways. Richer species are often the most abundant and show the highest contribution to pollination. Different species pollinate different species within a diverse agroecosystem. Also, different species visit preferentially different parts of the plant and thus contribute to a more thorough pollination. Different species respond differently to changes in climatic conditions and resource availability. They are also differently sensitive to the impacts of agricultural intensifications. Thus richer pollinator communities show higher resilience (Klein *et al.*, 2009).

Landscape structure and diversity determine the spatial and temporal availability of food, and sites most suitable for nesting, hibernating, and mating. Thus landscape quality is determinant for the maintenance of pollinators and the services they provide.

Wild and managed pollinators have suffered dramatic declines in recent years. Severe declines in *A. mellifera* populations, those of the major groups of pollinators and of the plants that they pollinate have been documented, despite the pervading lack of long term, globally distributed data (though the data records for *A. mellifera* begin in 1908). Land use change and changes in landscape structure are the major drivers of this change. Also, agricultural intensification, particularly the use of pesticides, that directly affect pollinator populations, and that of herbicides, fertilizers, irrigation, tillage, or fire, that affects the availability and spatial distribution of resources as well as environmental conditions, change the total abundance, composition, and richness of pollinator assemblages (Winfree *et al.*, 2009). Yet, the reduced amount of independent experiments or observations has hindered testing for the generality of the impacts of the above factors. To date, only habitat change has shown consistent negative significant effects on bee richness and abundance (Figure 4).

The above results show that pollinator decline is undeniable and that decline in the abundance and richness of pollinators has negative consequences for pollination. Yet, the consequent threats to global agricultural food production are still under debate.

Regulation of Human Infectious Disease

It is not possible to assert that the more diversity the better the regulation of human infectious diseases. In fact, evidence to date shows that the maintenance of some elements of biodiversity can cause disease, while the maintenance of other elements is key to regulating both the incidence and prevalence of disease.

Regulation of the appearance and transmission of infectious diseases to human populations is a regulating service. The service is provided by several processes such as the regulation of population sizes of vectors, hosts and pathogens, the regulation of interactions between them and human populations, and the regulation of their natural enemies.

Infectious diseases result from the interaction of pathogens or parasites, vectors, hosts, and the environment. Frequently many species are involved, including many hosts, many vectors, and a wide range of species with which they interact. Pathogens include helminthes, fungi, protozoa, viruses or prions, and bacteria or rickettsiae; bacteria and rickettsiae

Figure 4 Effects of different anthropogenic disturbance factors on (a) bee abundance (solid line) and (b) bee richness (dashed line). Mean effect and 95% confidence intervals are shown for each type of disturbance. Significant effects correspond to average and confidence interval values that do not overlap with the no-effect line. Numbers above each result indicate the number of independent measurements found in the literature used for the analyses (modified from Balvanera P, Pfisterer AB, Buchmann N, *et al.* (2006) Quantifying the evidence for biodiversity effects on ecosystem functioning and services. *Ecology Letters* 9: 1146–1156, clear open symbol, and Quijas S, Schmid B, and Balvanera P (2010) Plant diversity enhances provision of ecosystem services: A new synthesis. *Basic Applied and Ecology* 11: 582–593, solid symbol).

Table 3 Diseases whose transmission is affected by habitat or biodiversity loss and the associated mechanism. S indicates a suggested mechanism, while D denotes that mechanisms have been demonstrated in diverse studies

Disease	Mechanism	Main organisms that affects the disease
Coral diseases	Changes in host/vector abundance ^D	Coral reefs
Malaria	Changes in host/vector abundance ^D	Humans (mammals, vertebrates)
Helminthic parasite of fish	Changes in host/vector abundance ^S	Aquatic vertebrates (fishes and sharks)
Puccinia rust infection of ryegrass	Changes in host/vector abundance ^S	Plants
Amphibian limb malformation	Changes in host/vector/parasite behavior ^D	Amphibian (salamanders, frogs and toads)
Bacteriophage of <i>Pseudomonas syringae</i>	Changes in host/vector/parasite behavior ^D	Plants
Fungal disease of <i>Daphnia</i>	Changes in host/vector/parasite behavior ^D	Plank tonic crustaceans
Schistosomiasis	Changes in host/vector/parasite behavior ^D	Humans (invertebrates, vertebrates)
Trematode diseases of snails and birds	Changes in host/vector/parasite behavior ^D	Invertebrates, vertebrates
Hantavirus disease	Changes in host/vector abundance and host/vector/parasite behavior ^D	Humans (mammals, vertebrates)
Lyme disease	Changes in host/vector abundance and host/vector/parasite behavior ^D	Humans (mammals, vertebrates)
West Nile fever	Changes in host/vector abundances ^S , host/vector/parasite behavior ^S	Humans (birds, vertebrates)

Source: Modified from Keesing F, Belden LK, Daszak P, *et al.* (2010) Impacts of biodiversity on the emergence and transmission of infectious diseases. *Nature* 468: 647–652.

caused nearly 55% of infectious diseases. Zoonotic pathogens are those that complete their whole life cycle within animal species but can also infect humans, through links with other vertebrates. More than 70% of human diseases are caused by such pathogens associated to wild fauna, and their incidence is increasing with time (Jones *et al.*, 2008).

The nature of the links between biodiversity and the regulation of infectious diseases is quite complex. On one hand, higher biodiversity can be associated with a larger diversity of new pathogens; on the other hand, higher biodiversity has been associated with reduced transmission probability of already established pathogens and with the reduced establishment of new ones. Yet most evidence points to the latter. Mathematical models, individual studies, and recent syntheses have shown that a higher diversity of hosts is associated with less frequent and slower disease transmission, and thus reduced disease incidence (Keesing *et al.*, 2010).

At local to regional scales (Keesing *et al.*, 2010), biodiversity loss affects the emergence and transmission of infectious disease through changes in the abundance of hosts or vectors, changes in the behavior of hosts, vectors, or parasites, and changes in the condition of hosts or parasites (Table 3). Anthropogenic impacts on ecosystems have led to impacts on the regulation of infectious diseases through losses of natural enemies of vectors, increases in population densities of host species, changes in genetic diversity of vectors or pathogens (such as antibiotic resistant bacteria or pesticide resistant mosquitoes), as well as increased frequency of soil, water, or airborne transmission of pathogens.

At global scales, many social and ecological factors are related to the increasing incidence of infectious diseases (that peaked in the 1980s). The highest incidence occurs at high latitudes (30–60° N and 30–40° S), in areas with the highest population density. Yet, host species richness is a significant

predictor of the appearance of infectious diseases associated to zoonotic transmissions from wild species (Jones *et al.*, 2008).

Overall, reduced species richness has been related to increased disease incidence. Yet, further understanding of the role played by biodiversity in the regulation of infectious diseases is needed to better assess the risks of biodiversity loss on human health.

Analyzing the Links Between Biodiversity and Ecosystem Services at Different Spatial Scales

The links between biodiversity and ecosystem services have been studied at a wide range of spatial scales. The approaches used, hypotheses tested, and the types of results change clearly across these scales.

Local Scale

A large amount of work has been done to explore the links between biodiversity and ecosystem functioning at local scales, some of which has been used to assess the effects of biodiversity on ecosystem services. Experimental studies, observational studies, and modeling efforts have led to recent syntheses of this vast literature.

Qualitative syntheses have addressed the role played by various types of diversity. The first qualitative synthesis (Hooper *et al.*, 2005) emphasized the strong influence that species' functional characteristics have on ecosystem processes, independently of their relative abundance. Another one (Diaz *et al.*, 2006) suggested multiple potential links between genetic diversity, species richness, functional composition, and landscape structure on a range of ecosystem services. Yet the generality of the patterns was debated.

Quantitative meta-analyses have assessed the generality of the effects of species richness on ecosystem functioning derived from experimental studies. Higher plant species richness leads consistently and significantly to increased standing biomass of primary producers and increased efficiency in the assimilation of inorganic resources by these primary producers in terrestrial and aquatic systems. Data for other functions and groups is still insufficient to draw general conclusions (Cardinale *et al.*, 2011).

Experimental studies have also been used to assess the role of biodiversity in the provision of ecosystem services and synthesized using meta-analysis (Figure 5). Higher plant species richness leads to higher provision of plant products, greater pest regulation (lower primary consumer biomass), greater erosion control, and higher regulation of invasive species and pathogens. Also, increased mycorrhizae richness led to higher provision of plant products and higher erosion control. Yet, higher species richness led to lower low or non-significantly different soil fertility regulation (Balvanera *et al.*, 2006; Quijas *et al.*, 2010).

The effects of species richness on ecosystem stability, measured as the inverse of the variance of an ecosystem process through time, have been assessed in a few long-term experiments. Higher species richness led to higher stability in some cases and to nonsignificant changes in stability in others

(Balvanera *et al.*, 2006). Higher plant species richness consistently contributed to higher security (less variance) in the provision of plant products (Quijas *et al.*, 2010).

The above results are derived from extrapolations from links between ecosystem processes actually measured in experiments and ecosystem services that are potentially associated with them. Focusing on individual ecosystem service providers and making explicit these links has helped clarify these connections (Quijas *et al.*, 2010). Yet, direct measures of services from biodiversity experiments are needed.

Observational studies have in many cases measured ecosystem services directly. Recent syntheses for the case of agricultural food production, pollination, and regulation of infectious diseases have been summarized above. A meta-analysis of the effect of richness in tree plantations has shown that mixing tree species generally increases plantation growth rate.

Experimental and observational studies seldom address cultural ecosystem services. Yet, one experiment in temperate grasslands showed that people perceive changes in species richness, composition, and evenness. People were most attracted to the most diverse arrays (Lindemann-Matthies *et al.*, 2010).

Functional attributes of species and communities have strong influence on ecosystem service provision through their effect on ecosystem processes. A recent synthesis has shown that quantitative associations between species' traits and ecosystem services are available to date for a range of organisms, with a large proportion of data for plants and soil invertebrates. Key traits such as body size, canopy size, and specific leaf area or root architecture are related to a suite of ecosystem services (de Bello *et al.*, 2010).

Individual species have differential contributions to a particular function. The functional structure approach can be used to assess the relative contribution of each individual species to an additive ecosystem function, in the same way that rank-abundance curves assess the relative contribution of each species to the total abundance. Pollination in watermelon organic farms in California found within conserved matrices is provided by 11 bee species; eight of these species contribute with quite similar amounts of pollen grains. Instead, in organic farms found within agricultural matrices only four species pollinate watermelon; only one species contributes to more than 90% of the pollen grains deposited. Also, the relationship between species' relative abundance and relative functionality can be used to identify abundant species that are functionally important, or rare species that contribute little to the function, or species whose relative contribution to the function is significantly different than that expected by their relative abundance. Carbon stocks in the tropical rain forest of Chiapas, Mexico, are provided by 169 tree species; one abundant species with dense wood and large trunks, *Dialium guianense*, contributes to more than 10% of the abundance and of the carbon stocks; a fast growing species with thin stems, the pioneer species *Cecropia obtusifolia*, contributes less to carbon than expected from its relative abundance; various species of the genus *Ficus* contribute to less than 1% of carbon stocks and to less than 0.1% of the abundance, and yet

Figure 5 Effects of experimental manipulations of biodiversity on ecosystem services. Symbols show differential effects of trophic level manipulated: circle, primary producers; diamond, mycorrhiza; square, decomposer. Numbers above each result indicate the number of independent measurements found in the literature used for the analyses (modified from Cardinale BJ, Matulich KL, Hooper DU, *et al.* (2011) The functional role of producer diversity in ecosystems. *American Journal of Botany* 98: 572–592, and Chapin FS, Zavaleta ES, Eviner VT, *et al.* (2000) Consequences of changing biodiversity. *Nature* 405: 234–242).

have been considered keystone species due to their critical interactions with many bird and mammal species (Balvanera *et al.*, 2005).

Analyses of biodiversity effects on functions or services have mostly focused on a single function. Yet, a key question is how will species loss affect overall ecosystem functioning. Conceptual models and experimental studies have shown that increasing species richness increases the maintenance of multiple ecosystem processes; there are many species that contribute significantly to various functions (Gamfeldt *et al.*, 2008).

Evidence from local-scale experimental and observational studies points to positive effects of biodiversity on service provision, and to the paramount role played by species

composition or functional attributes. Key functional attributes such as leaf phenology, leaf distribution over stems and canopy size and architecture have been shown to be important in determining plant species' contribution to climate regulation (de Bello *et al.*, 2010).

Overall, while the local-scale experimental approaches may provide key insights on the way biodiversity relates to functioning, their potential applications to services is somehow limited. To date, only a small range of services have been assessed (e.g. soil fertility, fodder provision, biocontrol). Also, the realism of local scale biodiversity experimental manipulations and their potential applications to management relevant conditions, including larger spatial scales and human interventions, has been debated.

Landscape Scale

Analyzing the links between biodiversity and ecosystem services at landscape scales offers very different perspectives than those at the local scale. Although food production, or soil fertility regulation are provided at local spatial scales, many ecosystem services such as pollination, pest regulation, regulation of landslides or coastal protection depend on ecosystem processes and ecosystem service providers that occur at landscape scales. Mobile organisms that move freely through the landscape provide some of the services; the attributes of the landscape in terms of the types of land-use change found and their spatial arrangement are relevant at this scale; complex trophic cascades that encompass organisms with home ranges at a variety of spatial scales are associated with service provision. Also, societies and ecosystems interact at landscape scales through land-use decisions that often lead to land-cover changes or to agricultural intensification.

Natural experiments, those in which different diversity levels are found due to natural or anthropic causes, replace experimental manipulations of species richness at this scale. As a consequence, correlations between diversity and services can be observed, but can be the result of direct effects of changes in abiotic conditions on diversity, direct effects on the processes or services, or mediate the links between them. Testing for the underlying mechanisms is more complex. Yet, manipulations of some groups of species are possible at this scale.

Experimental manipulations of individual groups of species have shown positive correlations between diversity and ecosystem services. A meta-analysis of experimental bird exclusions in diverse agroecosystems in Central America showed that bird functional species richness, richness of functional groups and functional diversity were positively correlated with pest regulation services, measured as removal of arthropods (Philpott *et al.*, 2009). The contribution of all species and functional groups were not equal, and one species and two of the functional groups contributed disproportionately to the service. Yet, direct links to a service would require focusing on crop consumer arthropods.

Species loss at one particular trophic level can have cascading effects on many other levels, and thus have profound consequences on ecosystem services. Mathematical models have shown that many species of decomposers can be lost before observing a dramatic reduction in service provision; yet, the fraction of species lost that leads to reduction in ecosystem services increases as upper trophic levels are considered (plants, herbivores, and predators). Moreover, rapid declines in service provision are predicted as predators are lost (Figure 6). Given that the upper trophic levels are more vulnerable to land use change, as they have less functional redundancy, fewer individuals per species and are characterized by larger home ranges, rapid declines in ecosystem services are to be expected (Raffaelli, 2004; Dobson *et al.*, 2006).

Yet, the responses of ecosystem processes and services associated with species loss vary between different trophic levels. A meta-analysis of removal experiments in agroecosystems (Mooney *et al.*, 2010) showed that excluding vertebrate insectivores such as birds, bats, and lizards increased the abundance of predaceous and herbivorous arthropods, that is both those species that are considered pests in agroecosystems

(herbivores) and their natural enemies (predators); in fact, the strength of the effect of vertebrate insectivores on both groups was the same. Exclusions also showed reduced plant damage and increased plant biomass. Thus the role played by birds, bats, and lizards in pest regulation in agroecosystems can be seen both as positive (by decreasing herbivores, decreasing plant damage, and increasing plant biomass) and negative (by decreasing natural enemies of herbivores).

One of the main drivers behind species loss in terrestrial environments is habitat loss, or habitat degradation. Thus biodiversity effects on ecosystem services at landscape scales can be assessed indirectly through changes in land cover and in the spatial distribution of habitat patches. The mechanisms underpinning the maintenance of biodiversity in complex landscapes such as agricultural landscapes are increasingly being understood. Individual species' dynamics is given by that of individual populations that are found locally as well by the metapopulation, given by the group of populations found across the landscape. In similar ways, interactions among species within and among trophic levels occur at different spatial scale. Thus, structurally complex agricultural landscapes allow for the maintenance of biodiversity and are expected to contribute to the maintenance of ecosystem services such as pest regulation while ensuring food production (Tscharntke *et al.*, 2005).

One well-studied aspect of the role played by landscape structure on ecosystem provision is isolation from natural habitat. A meta-analysis of landscape effects on crop pollination services (Ricketts *et al.*, 2008) showed a consistent decline in pollinator richness with increasing isolation; richness drops to half of its maximum value at distances of 1500 m. A faster decay rate was found in visitation rate, which drops to half of its maximum value at a distance of 700 m, with steeper decay rates in tropical regions respective to temperate ones.

Ecosystem services can also be provided by the physical structure that results from the establishment and growth of species. That is the case of coastal protection which is provided by mangroves, salt marshes, coral reefs, and sea grass beds. Wave height decreases as it moves inland from a shoreline with mangroves or salt marshes. Decreases in wave height have been associated with increasing habitat distance inland from the shoreline for mangroves and salt marshes. Wave attenuation decreases with increasing water depth above sea grass beds and near-shore coral reefs, and with increasing grass cover in coastal dunes (Barbier *et al.*, 2008).

Given that changes in species richness, species' functional attributes and land cover characteristics are all relevant to determining change in ecosystem service provision, the integration of many of those aspects is needed to characterize the role played by biodiversity in service provision at landscape scales. Ecosystem processes and services are strongly determined by species' functional characteristics, or functional traits, and largely by those of dominant species. However, abiotic conditions can have direct effects on the services; also, nondominant species can have disproportionately large effects on the function. Thus the role played by biodiversity on ecosystem services can be explored using a step-wise analysis by dissecting the individual contribution of the above factors on ecosystem services, and then combining those into the

Figure 6 Declines in species diversity and corresponding impacts on ecosystem services for different trophic levels. A mathematical model suggests that declines in ecosystem services will initially be slow but will then accelerate as species from higher trophic levels are lost at faster rates and the consequences of their loss is most dramatic (modified from Dobson A, Lodge D, Alder J, *et al.* (2006) Habitat loss, trophic collapse, and the decline of ecosystem services. *Ecology* 87: 1915–1924).

best possible predictive model as has been suggested recently (Diaz *et al.*, 2007).

Spatially explicit models of the links between biodiversity and ecosystem services can be built based on the understanding of the tight links between land cover and ecosystem service provision, as well as those between species' functional attributes (Lavorel *et al.*, 2011). Thus land use can have both direct effects on ecosystem services, and those that affect species' functional attributes and in turn affect ecosystem service provision. Given that individual species' traits are relevant to various ecosystem services, and that land use change has impacts on multiple ecosystem services, models have been developed to assess the direct and indirect impacts of land use change on multiple ecosystem services. The recently developed tool to map and model ES called InVEST (Integrated Valuation of Ecosystem Services and Tradeoffs) uses LUC maps as a basis for further assessing quantitatively ES delivery in terrestrial and marine ecosystems.

At landscape scale the needs and perceptions of different social actors converge, each leading to different land use change decisions and fostering the provision of particular ecosystem services. Links between biodiversity and ecosystem services would then need to incorporate such complexity.

Relevant ecosystem services can be related to species' functional traits and functional diversity based on scientific evidence and local quantifications. Yet this can also be done from the perspective of the local social actors based on their perceptions of such links and their preferences for different ecosystem services. A conceptual framework that integrates all the above has been developed (Diaz *et al.*, 2011), that results from a combination of approaches into an interdisciplinary (ecological and social sciences) and intersectorial (scientists and relevant local actors) perspective of the links between biodiversity and ecosystem services (Figure 7).

Regional to Global Scale

From regional to global scales exploration of the links between biodiversity and ecosystem services is much more related to their potential spatial congruence than their functional relationships. The analyses rely on spatially explicit models that predict both biodiversity and service provision that are based on topographic, climatic, and land use information. The key question is whether most diverse areas are also those that are most critical for the provision of individual services or that of combinations of services. To date, less than

Figure 7 Diagrammatic conceptual frameworks for analyzing the links between abiotic factors (light gray), functional diversity (white), social-ecological interactions (black to white gradient) and ecosystem properties, and services (black). (a) Ecosystem services predicted from plant functional diversity (modified from Diaz S, Lavorel S, de Bello F, *et al.* (2007) Incorporating plant functional diversity effects in ecosystem service assessments. *Proceedings of the National Academy of Sciences of the United States of America* 104: 20684–20689). (b) Predicting ecosystem services from ecosystem properties, ecosystem management and species' functional traits (modified from Lavorel S, Grigulis K, Lamarque P, *et al.* (2011) Using plant functional traits to understand the landscape distribution of multiple ecosystem services. *Journal of Ecology* 99: 135–147). (c) Integrating ecological and social information about the links between biodiversity, ecosystem services and land use (modified from Diaz S, Quetier F, Caceres D, *et al.* (2011) Linking functional diversity and social actor strategies in a framework for interdisciplinary analysis of nature's benefits to society. *Proceedings of the National Academy of Sciences of the United States of America* 108: 895–902).

a dozen such studies are available at scales ranging from regional to global.

Spatially explicit models to predict the distribution of biodiversity have been developed for the past two decades. Instead, the development of analogous models for the case of ecosystem service delivery is very recent, and started to be developed only a decade ago. To date close to 50 different publications have addressed this issue from different perspectives. Yet, the broadest initiative to date on the subject, both in terms of the types of services analyzed, the range of data sources needed, and the number of places in the globe where it has been applied is the Natural Capital Project initiative (www.naturalcapitalproject.org). The initiative developed spatially explicit models for many ecosystem services as well as analytical tools to assess the management implications of the resulting maps (Kareiva *et al.*, 2011).

No consistent evidence of spatial concordance between biodiversity and ecosystem services has been found. This is true both for regions within a state (Chan *et al.*, 2006) and for the whole globe (Naidoo *et al.*, 2008). Also, the spatial patterns of provision of individual services are not correlated and thus critical areas for the maintenance of one service is not similar to that of another service (Chan *et al.*, 2006). When combining multiple ecosystem services with a total ecosystem service value the concordance between biodiversity and the services was not found either (Turner *et al.*, 2007).

The lack of congruence in the spatial patterns of biodiversity distribution and ecosystem service delivery is expected from a conceptual perspective. The lack of congruence in the spatial patterns of different groups of species was found a decade ago, and is consistent with the fact that each group is

differentially affected by changes in environmental conditions and that the scale at which such interaction is given changes with the size of the organism. In similar ways, the authors have seen here that different ecosystem service providers are relevant for the delivery of different services; ecosystem service providers and services respond differently to changes in environmental conditions and to anthropogenic disturbance.

Despite the lack of congruence in the distribution patterns of biodiversity and ecosystem services, management can be aimed toward maximizing the possibility of protecting both. Reserve selection algorithms have been used to identify the combination of areas that would maximize the conservation of biodiversity and the conservation of ecosystem services (Chan *et al.*, 2006). Spatially explicit models of biodiversity and ecosystem services have been used to predict the outcomes of different land use change scenarios and explore management alternatives that would maximize conservation of both biodiversity and ecosystem services. Stakeholder preferences for scenarios that provide multiple services while ensuring the conservation of biodiversity in a case study in the state of Oregon suggest opportunities for win-win policies that will ensure both (Nelson *et al.*, 2009).

To date, the identification of key areas of biodiversity or service provision heavily relies on the limitations inherent in the spatial modeling tools. In general, the analysis of different scales (total area studied) encompasses changes in the resolution (pixel size) of the study. Changes in resolution have been shown to lead contrastingly different patterns of concordance between biodiversity and service provision (Anderson *et al.*, 2009).

Understanding the links between biodiversity and ecosystem services at regional to global scales is still developing. Systematic comparisons with the equivalent methods are needed among regions and among scales. Also tools for this assessment might need to be refined.

Conclusions

Research available to date has shown that biodiversity plays a prominent role in the delivery of many key ecosystem services. A wide range of types of organisms, their genetic, population, and community diversity, as well as the landscape diversity and the trophic networks among them are the key ecosystem service providers. Biodiversity is linked to agricultural food provision, soil fertility regulation, pollination, and human disease regulation in a variety of ways; ongoing studies have contributed significantly to understand the ways in which biodiversity is important for ecosystem services. Most of the data available was derived from experimental manipulations of biodiversity and its effects on ecosystem services or on a few key ecosystem services. Direct measurements of a wide variety of ecosystem services are needed as well as more data at landscape scales, at which the most relevant connections between biodiversity and services are expected. Systematic comparisons of the role played by biodiversity at a set of spatial scales for many ecosystem services are needed. Also, the final effects on biodiversity and human well-being through ecosystem services are still to be fully understood.

Acknowledgments

We are very thankful to the many colleagues who have shaped our visions of the interactions between biodiversity and ecosystem services over the past few years. This paper constitutes a partial fulfilment of the Graduate Program in Biological Sciences of the National Autonomous University of México (UNAM). Biodiversity and Pest Control Services

Glossary

Agricultural intensification A process of change in crop and noncrop vegetation and management practices on farms. Changes in vegetation include reducing the numbers of crop species and varieties, and limiting trees, trap crops, and weeds. Other local changes in management include increasing the application of chemical pesticides and fertilizers, increased tillage and irrigation, and heavier mechanization. At the landscape level, intensification includes converting natural habitat to crop fields, destroying edge habitats, simplifying landscapes, avoiding fallows, and fragmenting natural habitat.

Agrobiodiversity Typically refers to the level of species diversity (with some research in this context on genetic diversity or diversity among communities and ecosystems).

At the species level, agrobiodiversity refers to species richness, species evenness, and community composition (or varietal richness, evenness, and composition) of both planned and unplanned vegetation, and all other organisms on a farm and in farming landscapes.

Biological control The use of naturally occurring or introduced natural enemies (e.g., predators and parasitoids) to suppress the populations of, and damage caused by, pests.

Complementarity Resource partitioning among consumer species that results in utilization of a greater extent of available resources.

Intraguild predation Species interaction where predators feed on herbivores as well as other predators, and where trophic levels are not well defined.

Introduction

A major focus of agricultural research is investigating the relationship between biodiversity and pest control. As natural systems are converted to agriculture, provisioning of some vital ecosystem services can decline (Kremen *et al.*, 2004). Ecosystem services, such as pest control, are ecosystem processes that improve and sustain human life (Daily, 1997). In agricultural systems, pest control problems may be exacerbated by biodiversity loss. Pests, defined as noxious weeds, insects, mites, and fungi, cause economic damage to crop plants (Hill, 1987). Many different forms of pest control are used, including cultural control, mechanical control, chemical control, and biological control. Biological pest control involves attempts to use natural enemies (e.g., predators and parasitoids) to suppress the populations of, and damage caused by, pests. Biological pest control has been used for centuries. Early records from ancient China (near 300 AD) indicate that farmers used ants as natural enemies in orange groves to control mite populations (Huang and Yang, 1987). Classical biological control has focused on introduction of species into agricultural areas in order to reduce pests to below economic damage levels. By the 1980s, 160 species of predatory arthropods and 16 insectivorous birds had been released for pest control in the USA (Letourneau *et al.*, 2009). To date, more than 2000 species have been released worldwide (van Lenteren *et al.*, 2006).

With agricultural intensification, use of biological methods of pest control has declined, being replaced with chemical control and the use of genetically modified organisms to combat pests (Benbrook, 2001). But such changes incur environmental costs and exacerbate biodiversity losses in agricultural landscapes (Bengtsson *et al.*, 2005; Relyea, 2005). Pesticides can cause reproductive problems for agricultural and off-farm biodiversity, and contaminate waterways significantly.

Secondary pest outbreaks, and nontarget mortality of natural enemies, often lead to increasing pesticide use, and continuing dependence on pesticides to combat ever-increasing pest loads (e.g., pesticide treadmill) (Van den Bosch, 1989).

Although ecological researchers have long maintained an interest in understanding relationships between diversity and trophic interactions, there is renewed interest in understanding natural processes of pest control in agroecosystems, due to growth of organic and ecological agriculture. Using biological control of pests necessitates understanding relationships between agricultural management, pest and natural enemy communities, and agricultural landscapes. Thus biodiversity impacts on pest control can be evaluated at a number of levels of biological organization (e.g., genetic diversity within a species, species diversity within a taxon, functional diversity within trophic level, and interactions within complex food webs) and at distinct spatial scales (e.g., farm plot, habitat, landscape, and region) (Letourneau and Bothwell, 2008) (Figure 1).

At the level of biological communities, agroecological research examines how two components of agrobiodiversity affect pest control. Planned biodiversity includes crop plants, other vegetation, and livestock chosen by the farmer to be in the agroecosystem. Associated biodiversity includes all other organisms that occur and survive in an agroecosystem depending on the management style chosen by the farmer and the surrounding landscape (Vandermeer and Perfecto, 1995). Thus researchers have focused on understanding how changes in agroecosystem management and agricultural landscapes directly affect natural enemies and pests, and specifically have examined the mechanisms underlying relationships between biodiversity of natural enemies, pests, and plants, and pest control services.

The study explores how biodiversity, both within farms and across landscapes, affects pest control. It focuses on how

Figure 1 Major influences of biodiversity (at several levels of biological organization and distinct spatial scales) on pest control. Each of the levels of diversity influence pest control in several ways and interact resulting in complex multitrophic interactions.

changes in crop and noncrop plant diversity, natural enemy diversity, and changes in diversity at multiple trophic levels result in complex effects on pest control. It then shifts to patterns beyond the farm by examining how landscape diversity including maintaining noncrop vegetation nearby to farm fields, proximity to natural habitats, and habitat heterogeneity affect pest control. Finally, the study discusses conservation biological control and provides some conclusions. Although pests occur in a variety of ecosystems, from a wide array of taxonomic groups, it focuses on insect pests in terrestrial agricultural systems, and includes examples from other systems and pests where relevant to inform the discussion.

Agricultural Intensification and Impacts on Biodiversity

Creation and intensification of agriculture result in biodiversity loss with important implications for pest control. Destruction of habitat, conversion to agriculture, and simplification of landscape structure are the principal causes for biodiversity declines (Harrison and Bruna, 1999; Bianchi *et al.*, 2006). Furthermore, agricultural habitats are created at an ever-accelerating rate (Bawa *et al.*, 2004), and agricultural intensification results in dramatic biodiversity losses (Letourneau and Bothwell, 2008). Although natural ecosystems have largely intact food webs, with naturally occurring processes that maintain pest populations at certain levels, natural control is lost with agricultural intensification (Swift and Anderson, 1993). Agricultural intensification refers to two general processes: (1) changes in the vegetation diversity in an agroecosystem (including crop species and varieties and other vegetation components such as trees, trap crops, and weeds) and (2) changes in management practices and intensity of production including soil amending, chemical use, tillage, and

irrigation, among others (Altieri, 1999). Agricultural intensification includes modifications at the local (e.g., shortening crop rotation cycles, decreasing crop diversity, increasing inputs, implementation of genetically modified crops, increased tillage, increasing field size, and increased mechanization) and landscape scales (e.g., converting natural habitat to fields, destroying edge habitats, simplifying landscapes, avoiding fallows, and fragmenting natural habitat) (Tschamtker *et al.*, 2005). Intensified, or modern, agriculture is highly simplified and includes low diversity of plant species and crop varieties (e.g., about 70 species are planted in 1440 million ha) (Altieri, 1999). The impacts of intensive agricultural production on biodiversity and ecosystem services are a major research focus.

Intensification affects biodiversity generally, but natural enemies, especially predator species, tend to be more strongly affected by habitat disturbance and loss leading to shifts in the ratios of prey to predator species, and subsequent effects for ecosystem processes (Bruno and Cardinale, 2008). A recent meta-analysis, covering 66 studies, found that both the species richness and abundance of predatory insects (as well as birds and spiders) was significantly higher in organic compared with conventional (or modern, intensive) farms, whereas the abundance of pest species and nonpredatory insects was higher in conventional farms (Bengtsson *et al.*, 2005). Specific groups of predators, such as carabids, are more abundant, diverse, and more evenly distributed in organic compared with conventional farms (Kromp, 1999). Frequently, organic agriculture benefits species richness and abundance of plants, predatory arthropods, and nonpredatory arthropods (Hole *et al.*, 2005; Letourneau and Bothwell, 2008). Other low-intensity agroecosystems, such as shaded tropical agroforests, harbor a high richness of predator species (e.g., ants and birds) (Perfecto *et al.*, 1996; Philpott *et al.*, 2008). Similarly, shade tree diversity within cacao agroforests positively impacts parasitoid wasp richness (Sperber *et al.*, 2004). The characteristics of organic farms likely to increase biodiversity of

natural enemies include agrochemical elimination, crop rotation, maintaining areas of seminatural vegetation, and preservation of mixed, or species-rich, farming (Hole *et al.*, 2005; Macfadyen *et al.*, 2009). In agroforests, increases in canopy diversity, density, and structural complexity correlate with increased predator diversity (Philpott *et al.*, 2008). Thus, less-intensive agricultural systems, such as organic and ecological farms, that include a high plant and natural enemy diversity, noncrop habitats, and landscape heterogeneity may support higher biodiversity, promoting pest control services. Despite the large number of studies that demonstrate higher abundance of natural enemies in organic farms, relatively few have examined differences in pest control, or cascading effects on crop yields (Letourneau and Bothwell, 2008). These and studies comparing pest control in diverse versus species poor farms, farms in simple versus complex landscapes, and the effects of releases of single versus multiple biological control agents are more common, and essential for understanding how pest control is affected by biodiversity.

Vegetation Diversity and Pest Control

The number of crop plants and varieties, weeds, planned weed strips, shade trees, and the temporal and spatial organization of plant species all affect pest populations and natural enemy assemblages. Andow (1991) reviewed the impacts of vegetation diversity on arthropod populations to test the resource concentration and natural enemies hypotheses proposed by Root (1973). The natural enemies hypothesis states that in polycultures (fields with multiple crop species), natural enemy abundance and diversity are higher due to more continuous food availability compared with monocultures (fields with a single crop species) (Root, 1973). The resource concentration hypothesis states that in monocultures, specialized herbivores have a more concentrated and unlimited food supply, thus supporting higher populations (Root, 1973). Thus, herbivore, or pest loads are affected by vegetation diversity in two major ways, with a number of possible mechanisms explaining each. Andow (1991) found that across 209 studies (and 287 herbivore species) reviewed, 51.9% of herbivore populations were denser in polycultures and 15.3% had higher population densities in polycultures. However, more herbivore species were found in polycultures than in monocultures. Across all studies, evidence indicated that both resource concentration and natural enemy increases suppress herbivores.

Crop Diversity

Increasing crop diversity can be accomplished across both space and time and can affect pest control via several mechanisms. Crop diversity can be altered by increasing the number of cultivars or varieties of a single species (e.g., increasing genetic diversity), increasing the species diversity of crops, adding crop rotations, and by increasing the architectural diversity of the crops. For several decades, scientists predicted that pest outbreaks should be more frequent in monocultures than in polycultures because crops associated with taxonomically diverse plantings will be less frequently attacked

than those associated with simple mixtures (Elton, 1958; Root, 1973). Andow (1991) reviewed several hypotheses of how crop diversity may reduce herbivore loads and increase natural enemies. Herbivores, especially specialists, he wrote, should be less common in polycultures because they have problems locating host plants, because host-location cues may be interrupted by the mix of plant species, and plant quality is more variable. Parasitoids and predators should better deter pests in polycultures because they can switch prey when certain species become rare, natural enemy reproduction takes place more often in polycultures, and there are alternative hosts in polycultures. Natural enemy populations are further benefited in polycultures because therein exist prey refuges that allow prey populations to survive, stabilize the population fluctuations between prey and predators, and thereby make continual prey suppression possible. Several studies show empirical support for these hypotheses.

Increasing crop diversity has variable impacts on herbivore populations. Increasing genetic diversity can protect crops from pests, including crop diseases. Increasing the crop species can limit the dispersal of disease spores, and at the same time increase crop yields (Altieri, 2004). For example, in a study in China, increasing rice varieties planted across a large area decreased attack by rice blast (by 94%) and increased yields (by 89%) compared with single-variety monocultures (Zhu *et al.*, 2000). Although examples with diseases are somewhat more common, increased genetic diversity can also hinder insect pests. Increasing the diversity of willows in a field decreases the population density, oviposition rate, and plant damage caused by herbivorous beetles (Peacock and Herrick, 2000). Large-scale increases in corn acreage for biofuel production (19% increase between 2006 and 2007 in the USA) have negatively impacted pest control, yet increasing varieties of corn planted may promote pest control (Landis *et al.*, 2008).

Intercropping, or the cultivation of two or more crops such that they interact biologically, can reduce pest populations by decreasing resources available, specifically to specialist herbivores. Intercrops can be mixed or in neighboring rows or strips, where crops are grown in the same field, or relay crops where crops are grown one after the other (Vandermeer, 1992). Myriad examples empirically demonstrate that pests are less abundant in intercrops due to mechanisms associated with the resource concentration hypothesis (Vandermeer, 1992); however, intercropping may increase resources available to generalist herbivores (Schellhorn and Sork, 1997; Zehnder *et al.*, 2007). Timing of planting and fallow lands (a temporary lack of crop diversity) can be very important in regulating pests as is discontinuity in monocultures (Altieri, 1999). Providing some permanent vegetation helps maintain populations of natural enemies (Altieri, 1999). Temporal increases in crop diversity from using crop rotations can diminish pest problems. Rotations, or successional changes in crop species planted in a single field, can minimize weed and disease problems and can lower insect pest populations (McLaughlin and Mineau, 1995, and references therein).

Increasing crop diversity can also lead to increased architectural diversity, or from a pest's-eye view, habitat complexity. Habitat complexity can strongly affect both the abundance and diversity of natural enemies and their ability to capture

prey items (pests). Langellotto and Denno (2004) examined the impacts within plant and within habitat complexity on natural enemy communities. They found that in seven of nine natural enemy guilds, and for natural enemies overall, increasing habitat complexity increased abundance, and decreasing habitat complexity lowered abundance. They also reported possible mechanisms for these observations and did not find that increased prey abundance mediated observed increases in natural enemy abundance. Instead, refuge from other predators, additional provided resources (e.g., alternative prey, nectar, and pollen), and more effective prey capture appeared to play important roles. In contrast, habitat complexity may hinder pest control if parasitoid host-location cues are interrupted, or if parasitoid search efficiency is reduced (Andow, 1991).

Other Vegetation in Crop Fields

Allowing noncrop plants to grow within crop fields can also increase natural enemy activity and decrease pest pressure. Diversity and abundance of weeds, and trap crops, in agricultural systems may also decrease pest densities because weeds may provide alternative resources for or otherwise harbor populations of natural enemies (Altieri, 1999). Especially in orchards and agroforests, natural enemy diversity may be higher, and pest populations lower, where weeds or other understory plants are maintained (Altieri, 1999). Adding strips of weedy plants into crops (including vineyards) can increase pest control services (Berndt *et al.*, 2002; Jacometti *et al.*, 2007). Weed strips, especially of perennial plants, can also provide habitat for natural enemies, and early sources of predators in to crop fields. The so-called “beetle banks” or strips of tussock grasses, for instance, are used throughout Europe to provide overwintering spots for predators of crop pests (Gurr *et al.*, 2003, and references therein). The location of such strips (often in the center of fields) can further enhance the degree to which pests are suppressed in the crops themselves.

Trap crops, additional plant species planted usually as decoys for pests, increase plant diversity in fields, can lower pest populations in crops, and often harbor natural enemy populations (Figure 2). Trap crops are used in a number of crops. In cotton fields in Australia, alfalfa strips are used to both attract cotton pests (e.g., *Creontiades dilutus*) and to provide habitat for natural enemies. When the alfalfa is mowed, natural enemies will move into cotton crops, thus this technique can be used to enhance biological control when needed (Gurr *et al.*, 2003). In citrus groves in China, an aster (*Ageratum conyzoides*) is commonly planted to encourage and stabilize populations of natural enemies of herbivorous mites (*Panonychus citri*) (Liang and Huang, 1994). However, increasing floral resources in agricultural systems may also benefit herbivores by increasing herbivore fitness or masking necessary host-location odors for the parasitoids (Lavandero *et al.*, 2006). In fact, some plant species used to increase parasitoid populations may simultaneously benefit herbivores, thus selection of the plant species used to enhance diversity and resources for natural enemies must be done with care (Lavandero *et al.*, 2006). Finally, alley cropping, or

Figure 2 A strawberry field in Watsonville, California, with sweet alyssum (*Brassicaceae*) featured prominently in the foreground. This plant species attracts beneficial insects (i.e., lacewings, syrphid flies) to the strawberry fields where they feed on pests and benefit the crop plant.

planting rows of woody plants in crop fields, can also reduce pest pressure. In a number of countries, legume trees are planted alongside maize crops which depending on the context can increase soil quality, reduce pest pressure, and increase natural enemy populations, or can increase seed predation on the crop, and increase root competition (Schroth *et al.*, 2000).

Natural Enemy Diversity and Pest Control

Ample research has examined the relationships between predator diversity and pest control (e.g., Pimentel, 1961; Root, 1973; Andow, 1991; Gliessman, 1989) and the complex interactions that arise between predator diversity and prey (Ives *et al.*, 2005, and references therein). Further, there is a long history of debate among experts in biological control, and conflicting evidence as to whether single or multiple species introductions of pest control agents are better for controlling pests (e.g., Cardinale *et al.*, 2003; Bianchi *et al.*, 2006). Increases in predator diversity do not always result in increased pest control over single-species treatments (Finke and Denno, 2004) and many biological control strategies prove successful with the introduction of just a few natural enemy species (Myers *et al.*, 1989; Denoth *et al.*, 2002). In fact, biological control strategies employed with multiple species can actually hinder biological control efforts (Denoth *et al.*, 2002). Yet, several empirical studies show that presence of multiple predators can enhance prey risk for important crop pests (Losey and Denno, 1998; Cardinale *et al.*, 2003; Schmidt *et al.*, 2003; Snyder and Ives, 2003). The variation in results, however, begs the question as to which mechanisms result in different outcomes in multipredator experiments.

There are several different mechanisms that could potentially contribute to both risk enhancement for prey (better pest control) and risk reduction (worse pest control). Both risk reduction and risk enhancement for pests can result in non-additive effects – effects that do not add up to the sum of their

parts (Sih *et al.*, 1998; Denoth *et al.*, 2002; Bruno and Cardinale, 2008). Risk enhancement can result from the sampling effect, facilitation, species complementarity, and increased abundance of predators. Risk reduction can result from antagonistic effects such as aggression, cannibalism, and intra-guild predation (IGP). Results from simulation models show that the sampling effect and complementarity among species tend to more strongly affect prey suppression than other mechanisms (Ives *et al.*, 2005). While different mechanisms may show prominence in certain studies or certain agroecosystems, it is likely that a variety of mechanisms operate simultaneously (Cardinale *et al.*, 2003). Each of these mechanisms and resulting effects is discussed in the following sections.

Mechanisms of Predator Diversity Effects

Sampling and Selection Effects

The sampling effect, also called the selection effect, selection probability, or lottery model, indicates that as richness increases, the chances of finding a species with strong or unique effects on lower trophic levels also increases (Huston, 1997; Ives *et al.*, 2005). Thus, in a community with higher biodiversity, it is more probable that one or two species responsible for large effects will be present. Sampling effects may occur where certain species have disproportionately large effects in a community, or where a single species has relatively greater abundance, prey capture ability, longevity, reproductive capacity, or competitive ability (Letourneau *et al.*, 2009). In biological control efforts, the sampling effect may be evident with releases of specialist species. In a review of natural enemy introductions to control agricultural pests, Denoth *et al.* (2002) found that in more than 50% of the successful introductions of multiple enemy species a single species was actually responsible for the successful control. They attribute this to the sampling effect whereby adding additional species increased the chance of having a useful one. Of course, sampling effects that result in introduction of a damaging or disruptive natural enemy could diminish pest control (Letourneau *et al.*, 2009).

Predator abundance usually increases as predator diversity increases, making it difficult to distinguish between the effects of abundance and richness, especially in field-based studies. Where correlations between natural enemy richness and pest control are encountered, increased pest control could result from simple increases in natural enemy abundance (Van Bael *et al.*, 2008). In the lab, experimental treatments can be set up to distinguish the two. With replacement designs, diversity is manipulated, but density or biomass of natural enemies is held constant. In additive designs, diversity is manipulated while initial density or biomass of natural enemies is held constant. Replacement designs are generally more useful for disentangling mechanisms of biodiversity and ecosystem function relationships, and specifically species-specific effects, whereas additive designs are more appropriate tests of complementarity or nonadditive effects (Ives *et al.*, 2005). In addition, additive designs more likely represent what is happening in agricultural fields with enhanced vegetation, predator refuges, and other complex structural components.

Facilitation

Facilitation occurs when two or more different species of natural enemies enhance the effect of another. There are many examples of predator facilitation in the literature that result in increased pest control. For example, predators that forage on vegetation (e.g., coccinellid beetles) will often scare pests (e.g., aphids) who then fall to the ground and are preyed on by ground-foraging carabid beetles (Losey and Denno, 1998). Thus the coccinellid assists the carabids to locate prey by chasing away aphids. Clearly, however, for such facilitation to occur and result in synergistic effects, in particular, the two predator species must forage in the same part of the season, at the same time of day, and not interfere with the prey capture rates of the other species (Losey and Denno, 1999).

Complementarity

Complementarity is based on the principle that as consumer species utilize different resources, thereby partitioning them, a greater extent of the available resources will be consumed (Loreau *et al.*, 2001). If a diverse suite of natural enemies partition resources, or are complementary, this may thus increase pest control. The effects of natural enemies that feed on different prey species, different life stages of a single prey species, or that forage or feed in different microhabitats of agroecosystems, or at the different times of day or seasons may combine in a complementary fashion (e.g., Bruno and Cardinale, 2008; Letourneau *et al.*, 2009). Complementarity often leads to increases in prey risk enhancement but may depend on the degree to which different natural enemies actually partition resources (Bruno and Cardinale, 2008). Although theory predicts that organisms partition resources, little empirical data support that complementarity increases pest suppression. This may be due to difficulty of assessing natural enemy diets and host preferences or because many studies are conducted in homogeneous agricultural fields without much option for partitioning (Ives *et al.*, 2005; Bruno and Cardinale, 2008).

Nonetheless, some studies show that species complementarity in diverse natural enemy assemblages increases pest control. Bogran *et al.* (2002) found that three species of parasitoids attacking a whitefly pest in cotton preferentially attacked larvae of different sizes and in spatially distinct areas of the cotton plants, thus leading to higher parasitism rates where all three species co-occurred. Finke and Snyder (2008) used an experimental test to separate the effects of species richness and resource partitioning and found evidence to support the latter. They released different mixes of specialist parasitoids (reared on one species of aphid hosts to which they show host "loyalty") and generalist parasitoids (reared on three aphid species) into large field cages with mixes of the aphids. They found that increasing the diversity of specialist parasitoids resulted in higher parasitism rates and lower aphid populations; however, increasing the richness of generalist species did not. Thus they empirically demonstrated the importance of resource partitioning as a mechanism driving biodiversity effects. Neumann and Shields (2008) found that releasing a combination of nematodes with complimentary foraging strategies (e.g., an ambush and a cruiser nematode) significantly reduced alfalfa insect damage compared with controls and one single-species treatment; however, not all

combinations of nematodes provided effective control. Finally, Williams-Guillén *et al.* (2008) compared the single- and multitaxon impacts of birds and bats on arthropod removal in coffee agroforests and found that each predator taxon provided higher pest control services during different seasons (birds during winter when migratory birds form a large fraction of the community). Further, likely because of the temporal separation in foraging times, birds and bats acting together had the greatest negative effect on arthropod loads.

Functional Diversity

Although species richness has been most often used as a metric of diversity, functional group richness has been invoked as a better predictor of ecosystem service as traits of organisms more strongly relate to functions than do taxonomic classifications (Tilman *et al.*, 1997; Diaz and Cabido, 2001). A functional group is a grouping of species based on similarity in behavioral, morphological, physiological, or resource use traits (Petchy and Gaston, 2006; Philpott *et al.*, 2009). Functional diversity of natural enemy characteristics, then, might be more important to consider than the taxonomic richness of predators itself, as this relates more strongly to ecosystem function (Hooper *et al.*, 2005).

Functional diversity, especially of important predators, may be more strongly affected by agricultural intensification than species richness. For example, Flynn *et al.* (2009) found that bird functional diversity declined with agricultural intensification more quickly than did species richness. Further, Schweiger *et al.* (2007) found that declines in specialist parasitoids were stronger than generalist parasitoids with habitat degradation. This may be especially important if species complementarity is an important mechanism maintaining positive effects of predator diversity on pest control. Philpott *et al.* (2009) examined patterns behind significant positive relationships between richness of insectivorous birds and arthropod removal in tropical agroforestry systems. They divided birds into functional groups based on characteristics related to predatory function (e.g., body size, diet, foraging strategy, and strata) and then correlated changes in functional richness with both species richness and pest control function. Species richness and functional richness were highly correlated across the nine study sites examined, and functional richness correlated significantly with arthropod removal. However, simple species richness remained a better predictor of ecosystem function than functional richness either because the traits included were not sufficient to explain all variation, or because presence of important predator species played a more important role.

Functional Redundancy and the Insurance Hypothesis

Functional redundancy may result in increased pest control under the insurance hypothesis. Functional redundancy, or a lack of complementarity among co-occurring species, indicates that natural enemies share traits such as similar foraging modes, diets, and strategies, and thus can be placed in the same functional group. Removing functionally redundant species from a community in theory has no effect on the ecosystem, whereas adding functionally redundant species can increase interspecific competition but does not affect pest control function (Straub *et al.*, 2008, and references therein).

However, agricultural systems are constantly disturbed, and even functionally equivalent species may respond differently to environmental changes (Perfecto *et al.*, 2004). Thus, the importance of maintaining functionally redundant species can be supported under the insurance hypothesis.

The insurance hypothesis suggests generally that functional redundancy is important for maintaining ecosystem services should conditions change (Yachi and Loreau, 1999). In the context of pest control, this means that as crops are harvested, fields are tilled, or as weed strips are mowed, the resulting changes to natural enemy effectiveness will be buffered by the presence of functionally redundant species within the agroecosystem. Functional redundancy has been inferred from studies finding no effect of increased predator diversity on pest control. In some cases, spider species richness does not affect predation (Sokol-Hessner and Schmitz, 2002) and the diversity of aphid-feeding natural enemies does not increase predation (Chang, 1996). But, functional redundancy is difficult to show unequivocally because neutral effects of predator species may result from a combination of other effects (Straub *et al.*, 2008).

Intraguild Interference

Intraguild interference refers to negative interactions between natural enemy species including predation, cannibalism, predator avoidance behavior, and predator–predator competition (Figure 3) (Lang, 2003). Among phytophagous insects released as biological control agents there is a very high degree of competitive interactions. Denno *et al.* (1995) found that in 91% of releases (45 studies), biological control agents competed with each other. If such interactions are sufficiently antagonistic, this may result in herbivore release and potential pest outbreaks, but depends on the nature of the interactions

Figure 3 *Azteca instabilis* ants attacking a lepidopteran larva in a coffee agroecosystem. Ants are often effective predators; however, they can interfere with the activities of other natural enemies such as parasitoids, spiders, and coccinellid beetles resulting, at times, in risk reduction for prey when in diverse assemblages. Photo by D. Gonthier.

involved (Rosenheim *et al.*, 1999; Snyder and Wise, 2001; Perez-Lachaud *et al.*, 2004; Ives *et al.*, 2005). IGP occurs where trophic levels are not clearly defined, and predator species feed on herbivores as well as other predators (Polis *et al.*, 1989; Rosenheim *et al.*, 1995; Ives *et al.*, 2005).

Interspecific interactions result in both enhanced and reduced prey risk. Herbivore suppression may decline due to IGP (Rosenheim *et al.*, 1995; Snyder and Wise, 2001; Finke and Denno, 2005). Finke and Denno (2005) examined the effects of several spider species, a coccinellid, and a mirid bug on prey in salt marshes and found that increasing spider richness reduced prey suppression due to both IGP and non-lethal effects of some spider species on others. However, the effects of IGP by spiders changed with habitat complexity; in complex habitats where mirids find refuges to escape spider predation, effects on herbivores were greater than in simple habitats where the combination of predator species resulted in risk reduction for prey (Finke and Denno, 2002). Ant foraging interrupts spiders, resulting in lower predation rates (probably due to both IGP and direct interference) (Halaj *et al.*, 1997). Pell *et al.* (2008) report that the exotic coccinellid predator *Harmonia axyridis* interferes with other predators via cannibalism, interfering with oviposition of parasitoids, and by feeding on parasitized pest eggs (coincidental IGP). IGP by the ladybeetle does not diminish with increased prey and contributes to its success as an exotic invasive species in agricultural landscapes (Snyder *et al.*, 2004). In contrast, IGP sometimes results in risk enhancement for prey. Lang (2003) investigated the interactions between carabid beetles and spiders (lycosids and lynphiids) in winter wheat. Carabid beetles negatively affected lycosid abundance, likely due to IGP, or by altering emigration rate of spiders out of carabid-free cages. In contrast, linyphiid abundance was not affected by the presence of carabids. Overall, predators did not negatively affect parasitism rates on aphids, and the overall impacts of predators, despite evidence of IGP, were synergistic resulting in higher predation rates where predator diversity was higher.

The strength of intraguild interactions in determining pest control outcomes is highly context dependent; effects vary with habitat complexity, prey density, type of IGP, and size and mobility of the intraguild predator and prey species (Müller and Brodeur, 2002; Pell *et al.*, 2008). Intraguild interactions most likely occur when natural enemies have similar hunting modes and foraging locations (Schmitz, 2007). Strength of intraguild effects also depends on plant architecture. In recently cut alfalfa fields, carabids are effective and quick predators on aphids, and also reduce predation rates leaving a longer term positive impact on pests (Snyder and Ives, 2001). Where plants are taller, carabids were no longer effective predators and still reduced parasitism thus having only negative impacts on biological control.

Finally, effects of IGP may be stronger for omnivorous rather than coincidental IGP. Coincidental IGP occurs where predators eat parasitized hosts, whereas omnivorous IGP occurs where predators consume other predators. Because coincidental IGP is coupled with direct predation on pests (e.g., intraguild predators eat prey and parasitoids simultaneously), omnivorous IGP most strongly interferes with pest suppression (Straub *et al.*, 2008). In biological control strategies, coincidental IGP actually can increase pest suppression

(Rosenheim and Harmon, 2006). Thus, in sum, even where IGP occurs, a diverse assemblage of predators may still promote better pest control than a species-poor assemblage without interspecific effects (Letourneau *et al.*, 2009).

Evidence that Predator Diversity Enhances Pest Control

Several compelling examples demonstrate that natural enemy diversity can enhance pest control, many from controlled lab and cage studies in temperate agricultural studies that are discussed above (*see* Facilitation and Complementarity). In addition, Cardinale *et al.*, 2003 investigated the effects of a coccinellid, a parasitic wasp, and the damselbug on pea aphids on alfalfa in large field enclosures and found increased pest control (and increased yields) when all three species were together. However, establishment rate of natural enemy species (for insect pests but not for weed pests) can be significantly lowered when multiple species of agents are released (Denoth *et al.*, 2002). This could be due to competitive exclusion, to bias in the data set, or due to the fact that managers often continue releasing agents in sequence until one is successfully established (Denoth *et al.*, 2002). Lower establishment could also be due to intraspecific aggression, or to IGP among agents released, or those already residing within the target agricultural systems, as discussed above (*see* Intraguild Interference).

Relatively little manipulation of predator diversity has been conducted in tropical agricultural systems, but there are increasing numbers of compelling examples from coffee and cacao agroforests that both invertebrate and vertebrate natural enemy diversity relates to increased pest control. Tylianakis *et al.* (2008) examined a number of agricultural systems (pasture, rice coffee, abandoned coffee, forest) and found that parasitism of nectar and pollen-feeding wasps was higher where parasitoid diversity was higher. Perfecto *et al.* (2004) excluded birds from coffee plants in Mexico and found that suppression of an artificial outbreak was greater in farms with higher diversity and abundance of birds. They attributed the increase in pest removal to increased abundance of a particular insectivore species in the more complex coffee habitat, thereby providing field evidence for the sampling effect. Borkhataria *et al.* (2006) found in shade coffee farms that birds alone and the combination of birds and lizards significantly reduced arthropod abundance (but not the abundance of parasitoids or arthropod predators), and that coffee leaf-miners responded weakly to predator removal. Further, the combination of birds and lizards was an additive effect. They concluded that vertebrate predator diversity is important in controlling pests, and that in their system, vertebrate predators do not disrupt arthropod natural enemies through IGP.

Several authors have conducted meta-analyses to review how biodiversity affects herbivore or pest densities. The results widely vary, perhaps due to the studies included, the criteria for inclusion of studies, or the experimental method used. Cardinale *et al.* (2006) reviewed studies to examine the effects of consumer diversity on resource depletion. Of 111 experiments, eight covered the effects of terrestrial predators on prey. Overall, a diverse mix of predators (> 3 species) removed prey better than a nondiverse mix, but prey suppression was not greater for a diverse mix than for the single best predator

species thus supporting the sampling effect. Schmitz (2007) examined studies specifically to evaluate support for different mechanisms driving multipredator effects. He found that in just under half of the studies examined (45.6%) that predator diversity resulted in risk enhancement or additive effects of predators, and in almost as many cases (40.3%), predator diversity resulted in risk reduction. He found widespread evidence for substitutable effects and for interspecific interference (including IGP) among natural enemy species; further, risk enhancement with multiple predator species was more likely in lab compared with field studies.

Finally, Letourneau *et al.* (2009) reviewed 62 studies, yielding 266 comparisons of diverse versus nondiverse mixtures of natural enemies. They found that in 69.5% of comparisons increased natural enemy diversity resulted in increases in pest suppression; in 30% of cases, increased diversity resulted in decreases in pest suppression. They also compared several study characteristics to determine how effects differed across system and location. In temperate areas, pest suppression as a result of natural enemy diversity was significant in agricultural systems, but not in natural systems, and pest suppression occurred in both temperate and tropical agricultural systems. Additionally, mean effect sizes (magnitude of pest suppression) were greater in cage compared with field studies. Thus a great deal of empirical evidence indicates that natural enemy diversity can enhance prey risk, but diversity effects are far from consistent.

One major limitation of studies conducted to date is the relatively low number of natural enemy species included in high-diversity treatments. In most meta-analyses, reporting the results of multipredator impacts on single prey species, the mean diversity of predators and parasitoids included is between three and four species (Borer *et al.*, 2005; Letourneau *et al.*, 2009). However, this is a far cry from the actual diversity of predators recorded, even in species-poor temperate agroecosystems. Natural enemy species richness for single herbivore species ranges from 13 to 86 species in several systems in the USA and northern Mexico (Letourneau *et al.*, 2009, and references therein). Further, when full prey–natural enemy communities are reported, numbers increase even more dramatically. More than 220 species of birds reportedly feed on agricultural pests in the USA (Letourneau *et al.*, 2009), and hundreds of species of predators feed on insect pests in tropical agricultural systems. Furthermore, the magnitude of diversity effects on pest suppression increases significantly with predator richness (Letourneau *et al.*, 2009), thus more studies are needed that manipulate a greater number of species in field or lab experiments, or new methods and models need be developed to examine the impacts of multiple predator species in highly species-rich communities.

Changes in Diversity at Multiple Trophic Levels

As agroecosystems are complex, so are the interactions therein, and interactions between diversity at multiple trophic levels may affect pest control. Differences in both plant diversity and predator diversity have distinct effects on pest populations. Yet, there may be complex interactions between diversity at different trophic levels that influences pests. Although many

focus on diversity at the natural enemy trophic level, it is clear from other work presented that plant diversity has strong bottom-up effects in agricultural systems (Root, 1973; Andow, 1991). Moreover, multipredator effects are rarely placed within the context of other interactions and most studies aimed at testing multipredator effects examine only predator, prey, and plant trophic levels. However, adding vertical diversity within food webs (e.g., a fourth trophic level) may alter biodiversity effects at lower trophic levels (Duffy *et al.*, 2007). In the few studies conducted to date, for example, addition of herbivore species can both weaken and strengthen the relationship between biodiversity and ecosystem function (Duffy *et al.*, 2007).

A few studies have examined whether the effects multiple predator species have on herbivores and plants may be altered by the presence of a larger predator species, or a parasite of one or more predator species, and those that manipulate diversity at multiple levels are rare. Aquilino *et al.* (2005) manipulated predator diversity (from one to three species) and plant diversity (from one to two species). They used three plant species (alfalfa, clover, and fava beans) and three predator species (two species of coccinellid and a damselbug). They found that increasing predator diversity resulted in an increase in predation on pea aphids (on both monocultures and polycultures), but that increasing plant diversity decreased predation rate by the same magnitude (in both single- and multipredator treatments). Negative effects of IGP on a single pest species may disappear in studies including alternate prey species (Schmitz, 2007) indicating that even simple changes to prey richness may affect the effects of predator diversity. Finally, Macfayden *et al.* (2009) used a food web approach to examine whether diversity changes at all trophic levels influenced whether organic farms are more resistant to establishment of novel pests. In comparing food web networks in 10 pairs of organic and conventional farms in England, they found that organic farms had higher richness of plants, herbivores, and parasitoid species. However, in farms with more species, food web connectivity was lower, and parasitism rates and numbers of parasitoid species attacking herbivores did not differ in the diverse organic farms and the conventional farms. Thus, in systems where complexity of an entire food web was examined, increased predator diversity did not necessarily result in increased pest control. Despite the difficulty in manipulating the vast array of species in multiple trophic levels, more complete investigation will be necessary for fully understanding how differences in diversity at multiple trophic levels affect pest control (Ives *et al.*, 2005).

Agricultural Landscapes and Biodiversity

Agricultural landscapes represent a wide variety of habitats including crops, noncrop vegetation patches, woodlands, wetlands, grasslands, and forests. In such landscapes, the presence of noncrop vegetation, the distance to natural areas, and the complexity of the landscape can all affect pest control.

Noncrop Habitats

Hedgerows, live fences, and other linear habitats within agricultural systems provide habitat for birds, bats, dung beetles,

and butterflies (Harvey *et al.*, 2005) and specifically for several groups of invertebrate natural enemies (Bianchi *et al.*, 2006). As agricultural habitats are constantly disturbed, hedgerows and other crop margins provide stable resource bases for natural enemies (Bianchi *et al.*, 2006). The characteristics of noncrop habitats that benefit natural enemies include providing alternate prey, nectar and pollen, nesting sites, and host plants necessary for reproduction and life-cycle completion (Landis *et al.*, 2000; Bianchi *et al.*, 2006), and are similar to benefits provided by vegetation diversity within crop fields. Hedgerows and field margins increase the movement of predators across agricultural landscapes similarly to how a high-quality matrix may increase movement of organisms between forest fragments (Vandermeer and Carvajal, 2001; Tschamtkke *et al.*, 2005). In some cases, increases in predator diversity in hedgerows can increase pest control. For example, linear vegetation strips in vineyards in California facilitate movement of natural enemies in the grapes, and thereby increase pest control (Benton *et al.*, 2003). Field margins and hedgerows can slow movement of fungal pathogens and can serve as barriers to the movement of pests, thereby improving pest control (Altieri, 1999). However, if the field margins provide alternative habitat for beneficial insects and other predators such that they forage more in the margins than in the crop, or prefer the crop-margin habitats more than the natural habitats, then this may harm pest control (Benton *et al.*, 2003; Bianchi *et al.*, 2006).

Proximity to Natural Areas

Distance to natural areas such as woodlands and grasslands can also affect pest control because natural enemies may find refuge in nearby natural habitats. Species of higher trophic levels, such as natural enemies, tend to be more strongly

negatively affected by isolation from natural habitats (Klein *et al.*, 2006, and references therein). These declines in richness are likely due to more unstable populations of predator and parasitoid species, increased energy requirements, and a lack of food and nectar sources when far from natural habitats (Klein *et al.*, 2006). In agroforest landscapes in Indonesia, both diversity of natural enemies and parasitism rates of trap-nesting hymenopteran brood declined with distance from forest, and for natural enemies, this landscape factor was a more important predictor than light intensity or the number of plant species in crop areas (Klein *et al.*, 2006). Furthermore, in coffee agroforests in Mexico, ant richness declines markedly with distance from forest fragments, especially in less diverse agroecosystems leading to less diversity of predatory species further from forest fragments (Perfecto and Vandermeer, 2002; Armbrrecht and Perfecto, 2003). Predation rates may also decrease with increased distance from noncrop habitats at field margins. Parasitism rate declines, likely because parasitoids (and predators) are more susceptible to habitat fragmentation than herbivores (Kruess and Tschamtkke, 1994; Bianchi *et al.*, 2006). Thus landscapes with a greater diversity of habitats, and especially with smaller habitat patches may be preferable for increasing natural enemy function.

Habitat Heterogeneity

At the landscape level, habitat heterogeneity can strongly benefit pest control services. Including a high degree of habitat heterogeneity in agricultural landscapes (including many different types of crop fields, natural habitat areas, hedgerows, fencerows, wetlands, etc.) can increase the diversity of natural enemies in crop fields, and also can provide stability of resources for maintaining natural enemy populations (Figure 4) (Altieri, 1999). Habitat heterogeneity increases

Figure 4 Two contrasting agricultural landscapes differing in habitat heterogeneity. The high heterogeneity landscape from Sumatra, Indonesia (a) contains a high diversity of both crops (banana, mango, coffee, and rice) and includes forest trees and weed patches. The low heterogeneity landscape (b) near Toledo, Ohio, shows large corn and soybean monocultures and a very small forest fragment. Most evidence indicates pest control is more effective in high diversity landscapes.

with increased number of habitats, and generally with smaller patch size; spatial arrangement of patches may also be important. In landscapes with small patches, natural enemies may be better able to reach all areas of a crop field, and colonize early in the growing season. Heterogeneous landscapes may support higher abundance and diversity of natural enemies simply due to the different preferences of different species for different habitats (Bianchi *et al.*, 2006). Boatman (1994) demonstrated that carabid beetles move from field margins approximately 15–30 m into field margins, and thus the locations of field margins could be maximized to increase the abundance of polyphagous predators. Furthermore, some natural enemies can move only short distances into crop fields from margins but the dispersal distances vary with species examined (Nicholls *et al.*, 2001; Bianchi *et al.*, 2006). Thies and Tscharntke (1999) studied the effects of habitat complexity of noncrop habitats and their role on oilseed rape crops. They found that presence of structurally complex noncrop habitats related to lower parasitism of the pest than presence of simple noncrop habitats nearby.

Even in intensive, extensive agricultural systems, landscape diversity can be important in promoting biological control. Marino and Landis (1996) explored parasitoid diversity and attacks in cornfields in Michigan embedded in complex (small plots with abundant hedgerows) and simple (large plots with rare hedgerows) landscapes near and far from hedgerows. They found that parasitoid richness was similar in both habitats, and parasitism rates were five times higher in complex than in simple landscapes, but that distance from hedgerows did not affect parasitism in either landscape. In the Midwest US, relative removal rates of aphid pests in soybean fields were increased by landscape diversity (e.g., number and evenness of different habitats) (Gardiner *et al.*, 2009). In addition, abundance of coccinellid beetles (the main predator encountered in soy fields) was positively affected by the amount of natural habitat in the surrounding area. Conversely, in these same landscapes, increases in area planted with corn (largely for biofuel production) resulted in strong decreases in biological control of soybean aphids due to declines in habitat heterogeneity and specifically losses of area formerly in fallow or conservation lands (Landis *et al.*, 2008).

A few recent reviews have specifically targeted effects of habitat heterogeneity at the landscape scale on pest control. Bianchi *et al.* (2006) conducted a literature review to examine the impacts of landscape complexity on natural enemy activity in relation to pest pressure. They defined complex landscapes as those with a high proportion of noncrop habitats (e.g., forests, hedgerows, tree lines, grasslands, wetlands, and fallows) and with small patches (large perimeter to area ratios). In 74% of the studies examined, pest control was enhanced in complex landscapes. Further, pest pressure (defined as population densities, crop injury, and survival and population growth rate of aphids) was reduced in complex landscapes in 45% of observations. They highlighted that landscapes with herbaceous vegetation (80% of studies with enhanced natural enemy activity), woody vegetation (71%), and landscape patchiness (70%) were those that most related to increased natural enemy activity.

Studies since this time have documented that parasitism rate increases with forest area (measured at multiple scales),

proximity to forest, and proximity to road edges (Bianchi *et al.*, 2008). But just as with relationships between natural enemy diversity and pest control, the mechanisms underlying relationships between landscape diversity and pest control services need to be more specifically examined. Benton *et al.* (2003) reported that a mosaic of farm fields connected by noncrop habitat benefits birds, predatory ground beetles, and spiders. Thus in sum, several aspects of agricultural landscapes, including noncrop habitat, and spatial structure of the landscape affect pest control services provided by natural enemies, and movement of natural enemies across agricultural landscapes (Tscharntke *et al.*, 2005).

Conservation Biological Control

Conservation biological control is a process by which managers manipulate plants and other aspects of agricultural landscapes in order to increase abundance and diversity of natural enemies (Barbosa, 1998; Fiedler *et al.*, 2008). Normally, managers increase enemy populations by planting nectar sources, floral resources, seed production, and plants that support alternative prey, or shelter (Landis *et al.*, 2000). Out of 34 studies that have evaluated the impact of habitat management (e.g., purposeful plant additions) to increase natural enemies, most have focused on just four plant species, all annual, and most not native to the study area (Fiedler *et al.*, 2008). One study did evaluate the effectiveness of several native perennial plants in attracting natural enemies compared with plants commonly examined in habitat management trials (Fiedler *et al.*, 2008, and references therein). Many of the native plants screened attracted high numbers of natural enemies, more so than the commonly used nonnative plants, and in addition, these other plants may provide additional ecosystem services (e.g., increasing pollinator abundance and rural beauty) (Fiedler *et al.*, 2008).

Because impacts of natural enemy richness on prey suppression are variable and context dependent, making clear recommendations to farmers is difficult. Understanding the traits that increase pest suppression is key (Straub *et al.*, 2008). If, for example, the selection effect is operative in a particular agroecosystem, one could recommend the important predator, rather than planning to conserve natural enemy diversity more broadly (Straub *et al.*, 2008). Likewise, promoting the conservation of functionally redundant species within a community should not negatively impact function, and to the contrary may improve pest control services if conditions change (Yachi and Loreau, 1999; Straub *et al.*, 2008). Further, there are often nontarget impacts of introduced biological control agents, and if many species need to be introduced, there is even greater chance of impacts on nontarget species (Denoth *et al.*, 2002). Thus, considering pest control using naturally occurring predators and parasitoids is important.

Conclusions

Several levels of biological and habitat diversity affect pest control in complex manners. Vegetation diversity including crop genetic diversity, crop species richness, and noncrop plants

in farm fields can increase the number and function of natural enemies in crop fields. Predator diversity is a strongly context-dependent predictor of pest control, sometimes resulting in increased risk for pests where functional richness or complementarity is high, or where single species of effective predators are found. Yet IGP and other interspecific interactions between natural enemy species may result in risk reduction. At the habitat level, vertical structure of crop plants, weeds, and shade trees may promote population stability and diversity of natural enemies. Landscape complexity, including incorporating hedgerows and other types of noncrop habitat, as well as maintaining highly complex landscapes with a high amount of natural habitat seem to best promote pest control services.

Pest control, however, as an important ecosystem service in human-managed systems, should be examined in a larger context. First, pest control has a long history, and has in agroecological farms moved away from a pest elimination mentality toward understanding complex ecological interactions. For example, in traditional Guatemalan agroecosystems, farmers have intricate knowledge of their agricultural systems, and insects that feed on crops; however, they do not consider them pests (Morales and Perfecto, 2001). Instead, they consider the multitude of techniques used (e.g., intercropping, natural composting, and allowing for survival of beneficial insects) as a way to keep the insects from becoming pests. Many traditional agricultural systems, which incorporate traditional knowledge, and high levels of planned and associated biodiversity have complex ecological webs that result in high levels of natural pest suppression (Gliessman, 1989; Vandermeer *et al.*, 2010). Thus considering not only strategies for eliminating pests, but also employing strategies to maintain complex food webs may be warranted.

Whatever pest control strategies are promoted should also be considered in the context of farmers whose livelihoods strongly depend on crop production. For example, Steffan-Dewenter *et al.* (2007) examined a number of ecosystem services provided in shaded and unshaded cacao agroforests in Indonesia. They discovered that conversion of forest to cacao systems negatively affected plant biomass and a range of ecosystem services, but had little effect on species richness of associated biodiversity, overall. Reducing shade cover in the cacao farms, however, resulted in nonlinear changes in biodiversity, ecosystem services, cacao production, and income. Reducing shade cover in cacao farms from 80% to 40% resulted in higher levels of ecosystem services provided, and marginal increases in income. Eliminating shade cover altogether (to 0%) drastically lowered ecosystem function, but boosted incomes by 40%, and thus provided obvious benefits to farmers, at the cost of other ecosystem benefits. Thus any strategy aimed at increasing pest control services, or conservation biological control need consider not only the ecological principles discussed here, but also the farmers' livelihood.

Glossary

First theorem of welfare economics If all goods are private and all private and social costs are equal, then an economy with a complete set of competitive markets operates in a way that is Pareto efficient.

Insurance A contract under which a person or institution buys the right to be compensated in the event of a specified harmful occurrence. The payment, referred to as the insurance premium, is paid before it is known whether the harmful event will occur.

Intellectual property rights The rights of developers of ideas and techniques to require payment for their use by others and to prevent their use by others unless such payment has been made.

Invisible hand The term used by Adam Smith to describe the capacity of a decentralized market system to attain efficiency.

Pareto efficient A pattern of operation of an economy is said to be Pareto efficient if it is impossible to change its

operation so that everyone gains or at least someone gains and no one loses.

Public good A good whose consumption is nonrival and nonexcludable. Nonrival means that one person's consuming it does not preclude another from doing likewise. Nonexcludable means that the provider of the good cannot ensure that only those who have paid can benefit from its provision. Knowledge is a public good: My knowing something does not conflict with your knowing the same fact, and those who develop knowledge cannot ensure that only people and institutions that have contributed to the costs can benefit. An apple, in contrast, is a private good: If I eat it, you cannot. Also, apple producers can ensure that only those who pay for them can eat them.

Social costs The total costs to society of an action. These may exceed (or in some cases be less than) the private costs, which are the costs of that action to the individual or institution executing it.

Many distinguished scientists have argued strenuously for the conservation of biodiversity as a significant human priority (Ehrlich, 1988; Raven and Williams, 1999; Wilson, 1988). Because economic activity is the main driver of biodiversity loss, such conservation would undoubtedly have important economic implications. It would require economic changes and would certainly be associated with economic costs, although these could be more than offset by the gains. The proposal implicit in these arguments is in effect that we—society—should “buy” biodiversity by changing our economic modus operandi and incurring conservation costs.

What are we buying if we make such a deal? What is the nature of biodiversity as an economic commodity and why does it matter? How would its conservation contribute economically to our well being? These are the themes I address in this article. I consider three issues:

What are the economic functions of biodiversity?

What kind of commodity is biodiversity?

Does our usual economic mechanism, the market system, have the capacity to appreciate the economic value of biodiversity?

In other words, I first characterize biodiversity from an economic perspective, and then consider the capacity of our main economic institutions to realize the value of biodiversity and ensure that it is treated in a way commensurate with its importance. With regard to the first of these tasks, assessing why biodiversity is important economically, I draw extensively on recent literature in ecology, which I do with some

trepidation because this is not my field of expertise.¹ However, this is unavoidable: A serious analysis of the economic contributions of biodiversity has to draw on scientific understanding of how diversity contributes to the functioning of the natural environments that provide crucial infrastructure to human societies.

I begin with an attempt to explain what biodiversity contributes, in economic terms, to human societies. Why is biodiversity important? The reasons can be classified under the following headings. Biodiversity provides or enhances:

Ecosystem productivity

Insurance

Knowledge

Ecosystem services

There is some overlap between these concepts, but nevertheless they are helpful as a guide to thinking through the issues. All of them are economically important categories.

Biodiversity and Productivity

How does biodiversity contribute to productivity? There is experimental evidence that plant systems with more biodiversity are on average more productive than those with less biodiversity. A good illustration of this is work done by David

¹My understanding of the relevant issues has benefited from conversations with Gretchen Daily, Paul Ehrlich, David Tilman, and Peter Vitousek.

Tilman at the University of Minnesota (Tilman and Downing, 1994; Tilman *et al.*, 1996, 1997). He planted many similar plots of land with a variety of grassland plants, some with many species and some with a much smaller number. Each plot was planted with the same mix year after year, and several indicators of plot performance were recorded, including the amount of biomass grown and the proportion of the nutrients available that were taken up by the plants. Biomass refers to the total dry body weight of the plants: It is a measure of the amount of carbon from the atmosphere that is photosynthesized into carbohydrate. Tilman and others performing similar studies found that, on average, during a period of about 20 years, plots with a more diverse collection of species performed better than those with a less diverse collection.

What does more or less diverse mean here? There are two dimensions to diversity: diversity of functional groups, or of plant types, and diversity of plant species within a functional group. Plants are classified into functional groups on the basis of their intrinsic physiological and morphological characteristics, such as whether they fix nitrogen, have three carbon or four carbon photosynthetic pathways, or are woody (Tilman *et al.*, 1997). These characteristics influence the plant's resource requirements, seasonality, and life history. A key aspect of diversity is measured by the number of different functional groups represented by the plants on the plot. This is called, not surprisingly, functional diversity. Species diversity refers to the number of different species within each functional group, or to the total number of species present. This latter measure is sometimes called diversity *per se*. Clearly, there is a correlation between diversity *per se*, the total number of different species present, and functional diversity. One cannot add more species without eventually adding more functional groups as well. Another related determinant of productivity is the composition of the functional groups present: Productivity may depend not only on the number of such groups represented but also on their identities because some groups may be more important than others in contributing to productivity or resilience.

The average amount of biomass grown per year on a plot of a given size increased with the diversity of functional groups represented, as shown in Figure 1. The increase leveled off after a certain point. Tilman and co-workers also found more nutrient uptake and better soil quality on plots with a more diverse collection of plant species. Furthermore, the plots that were more diverse in this sense were also more robust in the face of climatic fluctuations. It appears from this work that both functional diversity and species diversity are important in maintaining productivity and resilience. Having functionally similar plants that respond differently to environmental fluctuations contributes to resilience. It ensures that whatever the environmental conditions, there will be plants of a given functional type that thrive under those conditions. The functional composition of the community will therefore not be changed by environmental fluctuations. In contrast, if the members of different functional groups respond differently to environmental fluctuations, then these fluctuations will alter the functional composition of the community and therefore its ecological characteristics, and it will be less resilient in the face of such fluctuations (Chapin *et al.*, 1997). Chapin *et al.* (p. 503) argue that

Figure 1 Average amount of biomass grown per year on a plot of a given size.

Genetic and species diversity *per se* are important to long-term maintenance of community and ecosystem structure and processes. This argues that no two species are ecologically redundant, even if they appear similar in their ecosystem effects under one particular set of environmental conditions.

What is the mechanism behind these results? There is still dispute about this. One possibility is that each plant type has a range of climatic conditions to which it is best suited. Climate varies from year to year in terms of temperature, rainfall, and in many other ways, and if a plot contains only one plant type then in many years it will not have any plants well adapted to the climates of those years. If, however, a plot carries many types, then in most years there will be some that are well adapted to the climate of that year, and on average its productivity will be greater. This is another illustration of the old proverb, "Don't put all your eggs in one basket." Analytically, it illustrates the same point as the economic argument for holding a diversified portfolio of stocks. The more diversified the portfolio, the less vulnerable one is to conditions that are bad for particular stocks or stocks in a particular sector of the economy. A robust portfolio should have stocks that do well in times of growth, stocks that do well in times of high interest rates, and stocks that do relatively well in times of recession. It should have different types of stocks. Diverse plots will also be more resilient to climatic variation, as a part of the same phenomenon. This is related to the insurance role of biological diversity, here manifested as higher average productivity. An alternative explanation for the greater productivity of mixed plant communities has been suggested based on the interactions between the fungal communities associated with the roots of the plants and the diversity of the fungi in the soil, which affects the effectiveness of nutrient uptake (van der Heijden *et al.*, 1998; Read, 1998).

Similar studies have been conducted for microbial communities and have found similar results. Again, they show that more diverse communities are on average more stable and robust in the face of environmental fluctuations (McGrady-Steed *et al.*, 1997; Grime, 1977; Hooper and Vitousek, 1997; Naeem and Li, 1997).

There are other arguments about why diversity raises productivity, mostly specific to particular biological communities. Trees in forests provide a good example. Some trees are tolerant of shade and others of bright light. A forest of a uniform tree species will consist entirely of trees of one of

these types. In contrast, consider a forest with tall shade-intolerant trees forming the upper canopy. These need bright light and in the upper canopy leaves receive this light. Below them are shorter trees that are more shade tolerant, and perhaps below these is another layer of even more shade-tolerant trees or shrubs. With such an arrangement of diverse species, bright light falls on those that most need it, and the light that passes through their canopy and is of lesser intensity then falls on plants well suited to it. Total photosynthesis—that is, conversion of carbon dioxide in the air to carbohydrates with the aid of light energy—will be greater under such a regime than in a single-species forest (Aber and Melillo, 1991).

These arguments show that diversity is important in ensuring the productivity and robustness of natural plant communities, and therefore of the ecosystems that are based on them. Diversity also helps natural ecosystems to make the best adjustments to conditions that vary over time or over space. Without the appropriate level of diversity, natural ecosystems cannot adjust to natural variations in the environment.

Through its role as the raw material in plant breeding, biodiversity also contributes substantially to the productivity of agricultural systems. New and higher yielding plant and animal varieties are generated from the natural variation in plants and animals. The large increases in grain yields of the “green revolution” of the 1960s and 1970s, which were responsible for keeping food output increasing in parallel with populations in developing countries, were largely achieved by use of genetic diversity in the plant populations. Estimates suggest that as much as \$1 billion has been added to the value of the U.S. agricultural output each year for the past half century as a result of plant breeders’ use of genetic diversity. Specifically, in the past half century there has been a doubling in yields of rice, barley, soybeans, wheat, cotton, and sugarcane; a threefold increase in tomato yields; and a quadrupling in yields of maize, sorghum, and potato (U.S. Congress Office of Technology Assessment, 1987). All this has been based on and derived from genetic variability in the underlying plant populations. In economic terms, this variability is an asset—and one that has yielded a high return at little cost. Diversity also contributes to productivity in agriculture through the practice of crop rotation. Changing from one crop to another from one year to the next can enhance soil productivity by increasing the nutrients in the soil. For example, rotating a crop such as wheat with a legume that fixes nitrogen can prevent long-term nitrogen loss and reduce the need for nitrogen fertilizers. This type of crop rotation was characteristic of traditional agricultural practices in medieval Europe.

It is important to note that although biodiversity contributes to the productivity of both natural ecosystems and agricultural systems, it does so through different mechanisms. Natural systems benefit directly from a diverse mix of species: Agricultural systems benefit from the existence of a pool of genetic variability on which breeders can draw. Agricultural systems are usually monocultures, consisting of a single species grown intensively over a large area. Its growth is supported by applications of water, fertilizers, pesticides, and weed killers. Farmers manage cropland so as to ensure that crop growth is not limited by lack of water or nutrients, and that the main food crop does not have to compete with other species or with pests during its growth. Farmers create and maintain an

artificial environment and then plant a crop that is optimally adjusted to this environment—an approach that is radically different from the natural growth process.

Biodiversity and Insurance

A dramatic illustration of the insurance role of biodiversity comes from the recent history of rice production. The prosperity and comfort of literally billions of people depend on the rice harvest. In the 1970s, a new virus, the grassy stunt virus, carried by the brown plant hopper, threatened the Asian rice crop. This appeared to be capable of destroying a large fraction of the crop and in some years destroyed as much as one-fourth of the crop. Developing a form of rice resistant to this virus became of critical importance. Rice breeders succeeded in this task with the help of the International Rice Research Institute (IRRI) in the Philippines. The IRRI conducts research on rice production and holds a large seed bank of seeds of different varieties of rice and the near relatives of rice. In this case, the IRRI located a variety of wild rice that was not used commercially but which was resistant to the grassy stunt virus. The gene conveying resistance was transferred to commercial rice varieties, yielding commercial rice resistant to the threatening virus. This would not have been possible without genes from a variety of rice that was apparently of no commercial value. Without this variety, the world’s rice crop, one of its most important food crops, would have been seriously damaged. Interestingly, the variety of wild rice that was resistant to the virus was found in only one location—a valley that was flooded by a hydroelectric dam shortly after the IRRI found and took into its collection the critical rice variety. The same situation was repeated later in the 1970s, and similar situations have occurred with other food crops, particularly corn in the United States (Myers, 1997). There is every reason to expect that events such as these will recur regularly: Planting large areas with genetically identical plants greatly increases the chances that once a disease starts it will spread with dangerous speed through the entire area and crop. A report by the Committee for Agriculture, Science and Technology (1999, p. 13) emphasized this point:

Because of the increasingly high densities and large areas over which they are now grown, both livestock and crop plants are continually acquiring new diseases and pests, and existing diseases and pests are continually evolving new strains that overcome the defenses of particular breeds or strains. This is exacerbated by the accidental transport of diseases around the world. These diseases and pests destabilize agricultural systems. For instance, areas of western Minnesota and eastern North and South Dakota no longer can produce viable wheat and barley crops because of new strains of scab and vomit toxin for which no crop varieties have sufficient genetic resistance. Indeed, catastrophic attacks of disease, invasions of insects, and climatic extremes have caused wholesale crop destruction and ensuing famines whenever crops had insufficient diversity to provide at least some plants with the ability to withstand the assaults. Outbreaks of avian flu in the Chesapeake Bay area regularly result in rigorous quarantines of poultry houses due to the extremely high density of poultry farms in this region.

Disease problems, as old as agriculture, are recorded in myth and in written history, and still exist. Red rust on wheat in Roman times, mass poisoning from ergot-tainted rye during the middle ages, the Irish potato famine of the 19th century, and the Southern

corn leaf blight in 1970 all were due to insufficient biodiversity in the affected crops. The severity of the 1998 Hong Kong chicken epidemic was likely exacerbated by the lack of diversity in disease resistance as well as by the high chicken densities in the production facilities.

The continual accrual of new diseases can be countered only if breeders can find sufficient genetic diversity within a crop or its relatives. Even the full complement of natural genetic variation, though, may not be sufficient to stop some diseases. Consider, for instance, the impacts of chestnut blight, an introduced disease that devastated what was once the dominant tree of the eastern United States, but which now occurs only as rare stump sprouts. Despite the vast geographic expanse and genetic diversity of the native North American chestnut, there is no known genetic resistance to its pathogen. Similarly, in vast areas of west and central Africa, livestock genetic resistance to the debilitating effects of trypanosomiasis is found only in a few unproductive local breeds. Despite massive efforts, the genetic mechanisms governing this resistance are not yet well understood.

A lethal disease of corn, or wheat or rice, were it to appear, would devastate agriculture and human society. The only insurance that society has against such a catastrophe is biodiversity. Genetic diversity within a crop plant or animal species and its relatives might allow resistant strains to be discovered and used. Similarly, a diversity of potential food plants might allow another species to become an effective substitute for a major crop species that was lost to disease.

These cases illustrate clearly the insurance role of biodiversity. It is an important defense against disaster in the form of new diseases. The pathogens that cause disease are evolving continually, in an attempt to outwit our defenses against them. A clear example of this phenomenon is the evolution of antibiotic resistance among bacteria. The bacteria that cause several once common diseases in humans are now showing resistance to their principal controls, to the great concern of public health authorities. The same is happening with the pathogens that cause disease in crops and in commercial animals. Without reserves of genetic variability we may not be able to develop varieties of our agricultural crops and animals that can resist these new disease varieties. Indeed, it is precisely genetic variability in the pathogens that allows them to develop resistance. Genetic variability means that some of the disease-causing pathogens are naturally relatively unaffected by our defenses against them, which may be in the form of weed killers, insecticides, or vaccinations for livestock. These more resistant specimens are the ones that survive and from which new subsequent generations are bred. Therefore, pathogens use against us the mechanisms that we will use against them if we preserve and use genetic diversity. Without this diversity, we have disarmed unilaterally in the war against our most threatening enemies.

There is another important role for the insurance provided by biodiversity—to provide variability that could be critical in responding to the environmental changes wrought by humans. Human activity is changing the climate and the sea level, and it is making many more local changes in the environment. A hotter climate may require different crop varieties. An increase in sea level may lead to increased salinity in groundwater, and therefore to a need for crop varieties that are salt tolerant. A good example of the value of diversity in the context of a changed environment is the evolution of plants that have grown on mine wastes in the United Kingdom. These wastes are rich in heavy metals and are poisonous to most plant species

(Antonovics *et al.*, 1971). The existence of a pool of genetic diversity allows us to find plants that could tolerate these poisons and even help to remove them from the soil. We are making changes to the global environment on an unprecedented scale, and biodiversity might be critical in allowing us to respond to the consequences of these changes. Population growth and environmental change mean that we now need the insurance provided by biodiversity more than ever before.

Biodiversity and Genetic Knowledge

The third reason I previously gave for the importance of biodiversity is that it is a source of knowledge. We can learn from natural organisms how to make chemicals that have important and valuable properties. A good example is provided by the polymerase chain reaction (PCR). This reaction is central to culturing DNA specimens for analysis—as in forensic tests used in trials such as the O. J. Simpson trial, and in many processes central to the biotechnology industry. Culturing requires an enzyme that is resistant to high temperatures. Enzymes with the right degree of temperature resistance were found in hot springs in Yellowstone National Park, and the heat resistance of these was then used to create an enzyme that could be used to culture DNA specimens. This enzyme is now central to the rapidly growing biotechnology industry. There are many more less complex examples. In fact, 37% by value of the pharmaceuticals sold in the United States are or were originally derived from plants or other living organisms (Carte, 1996). Aspirin is derived from the bark of willow trees. The bark of yew trees has been used to derive a drug that is effective against ovarian cancer (Stierle *et al.*, 1993). A derivative of the rosy periwinkle flower is being used to cure childhood leukemia. The key point is that certain plants and animals are known to produce substances that are highly active pharmacologically. Plants that live in insect-infested areas produce substances that are poisonous to insects, and these have been used as the basis for insecticides. Some snakes produce venom that paralyzes parts of the nervous system, and others produce venom that reduces blood pressure. Some insects produce anticoagulants. All of these have been adapted for medical use. There is little that is new in these observations: They form the basis for many traditional medicines, which rely heavily on plants. Shakespeare refers to this in *Romeo and Juliet* (II: iii):

O! mickle is the powerful grace that lies
In herbs, plants, stones and their true qualities:
For nought so vile that on earth doth live
But to the earth some special good doth give,
Within the infant rind of this weak flower
Poison hath its residence and medicine power.

Biodiversity and Ecosystem Services

I previously mentioned the role of genetic diversity in providing raw material for selective breeding, the traditional way of developing new crop or animal varieties that are more productive, more disease resistant, hardier, or more desirable in some other way. I have also mentioned its role in ensuring

the productivity of ecosystems, and in ensuring their robustness against diseases and pathogens. There are other more complex ways in which biodiversity is essential to the proper functioning of ecosystems and to the delivery of the ecosystem services on which human beings are so dependent.

There are cases in which the full diversity of organisms in an ecosystem is required for that system to function and to provide services to human societies, and the removal or addition of even a single type of organism can have extraordinarily far-reaching consequences. "Keystone species" provide a convincing illustration. Ecologists use the term keystone species to describe a species whose removal will cause an entire ecosystem to change substantially. A widely cited example is that of sea otters on the California coast. The removal of sea otters as a result of hunting them for their pelts led to far-reaching and undesirable changes in the California coastal ecosystems. Sea otters eat sea urchins, which in turn graze on kelp plants. Without control of the urchin population by otters, the urchins will destroy the kelp beds, completely changing the marine coastal environment. Removal of otters led to a greatly impoverished coastal environment, which was restored in part to its original state with a ban on otter hunting. Another example of the role and impact of a keystone species is provided by the removal of kangaroo rats from an area of the Chihuahuan desert, which led to a threefold increase in the yields of grasses and to far-reaching changes in the desert ecosystem. In this case, the rats had played a key role by eating seeds and disturbing the soil, and their removal consequently changed the plant balance (Power *et al.*, 1996).

Not only can the removal of a species lead to major changes in an ecosystem but also the introduction of a new species (a so-called exotic species) can lead to a profound transformation of the system. A dramatic example is the introduction of the rinderpest virus into East Africa in 1890. This initially attacked domestic and wild cattle and then spread. By 1892, 95% of the wildebeest in the Serengeti region had died, in addition to most of the domestic cattle. Wildebeest are one of the main grazers and also the main food sources for carnivorous predators (lions, leopards, and hyenas) in the Serengeti; therefore, their virtual elimination led to profound changes in the system. In the 1930s, the introduction of a vaccination against rinderpest reestablished the original system (Aber and Melillo, 1991). The point of these examples is that we cannot easily tell *a priori* which species are essential and which are not. There is often a risk that an apparently small change in a set of species will have effects far beyond those initially anticipated. The degree of interdependence between different species is great; therefore, human beings may depend on many more species than we would expect from a first analysis of the situation. Abelard (an eleventh-century French theologian) suggested that any organism has a role to play and a reason for existing: "Whatever is generated is generated by some necessary cause, for nothing comes into being except there be some due cause for it" (as quoted in National Research Council, 1999). Also, John Donne (as quoted in Hemingway, 1940), an English metaphysical poet of the seventeenth century, wrote that

No man is an island, entire of itself; every man is a piece of the continent, a part of the maine; if a clod be washed away by the sea,

Europe is the less, as well as if a promontory were, as well as if a manor of thy friends or thine own were; Any man's death diminishes me, because I am involved in mankind; And therefore never send to know for whom the bell tolls: It tolls for thee.

There is an ecological equivalent to this: No species is an island, entire of itself, not even *Homo sapiens*. Any species' extinction may diminish us because we depend on many species. To repeat: The loss of even apparently unimportant species can have immensely costly consequences because of the complex patterns of interdependence between species. In the end, the loss of an apparently small and unimportant group of species could threaten the provision of ecosystem services that are essential to humanity. The distinguished biologist E. O. Wilson once said of microbes that "We need them but they don't need us." This is why many scientists see a serious risk in the current rate of species extinction: They cannot be precise about the dangers involved but nonetheless believe that there is a real risk of costly consequences. To give this point some substance, I mention a possible relationship between the extinction of passenger pigeons and the introduction of Lyme disease into American society. When Europeans first arrived in the United States, the passenger pigeon was probably the most abundant bird in the country. Its population was estimated in the billions. It traveled around in flocks of hundreds of thousands, flocks so large that their passing darkened the sky for many minutes at a time. By 1914 they were extinct, annihilated by a combination of hunting and destruction of the habitat that they needed for survival. It seemed unbelievable that an animal so abundant could be reduced to extinction so fast. A possible connection between this extinction and the emergence of Lyme disease events has recently been proposed. A letter to *Science* in 1998 made the following suggestion (Blockstein, 1988, p. 1831):²

There is another possible twist to the complicated ecological chain of events presented by Clive G. Jones *et al.* (Reports, 13 Feb., p. 1023) whereby the incidence of Lyme disease might increase following population increases of mice allowed by a big mast year of acorns. A major competitor of deer and mice for these bumper crops has been absent from the eastern deciduous forests for a century. The extinct passenger pigeon (*Ectopistes migratorius*) was a nomadic wanderer that specialized on a diet of the superabundant, but unpredictable, crops of mast. With a population estimated at 2 to 5 billion, concentrated in enormous flocks, passenger pigeons congregated wherever there were huge crops of mast. The birds were so efficient at denuding the woods of nuts that many observers noted that native wildlife and feral hogs could not find sufficient food after a pigeon flock had passed through. Is it possible that, in the presence of passenger pigeons, the population explosions of mice in mast years, reported by Jones *et al.* would have been less likely. Could the outbreaks of Lyme disease in the late 20th century have been a delayed consequence of the extinction of the passenger pigeon?

The point here is that passenger pigeons ate acorns and beechnuts, both of which were abundant in the forests of the northeastern United States. The demise of the pigeons led to an increase in the food available for other animals that ate these, including mice. Mice are the main breeding ground and hosts of the parasites that cause Lyme disease, and it is reasonable that the explosion of food for mice led to an increase

²I am grateful to Paul Ehrlich for this reference.

in their population and thus in the population of Lyme disease vectors. (Abundant acorn crops always lead to increases in the population of mice.) The disease vectors transfer from mice to deer, which browse in the same forests and on the same foods and then move across territory likely to be used by humans, grazing on grass on lawns and fields. Therefore, the extinction of passenger pigeons could have been instrumental in causing the spread of Lyme disease to humans. This illustrates well the extraordinary complexity of the web of life and of the connections between different species and between species and human welfare. No one could reasonably have anticipated this connection between passenger pigeons and Lyme disease. No analysis of the consequences of the loss of this bird could have anticipated such an outcome. Indeed, the bird was so abundant that it must have been difficult to anticipate that human activity could drive it extinct.

The message of these examples is that it is difficult to foresee the consequences of a change in the biodiversity of an ecosystem. Even an apparently small change can lead to dramatic alterations in the system's ability to function and to provide the services on which human beings are dependent. There is another aspect of this phenomenon. A particular role in an ecosystem may be played at different times or in different circumstances by quite different plants or animals. The type of tree that stabilizes soil on a north-facing slope at a certain latitude may not grow on a south-facing slope at that latitude so that a different species is needed there to maintain the physical stability of the system. As a consequence, the set of species required for a certain type of ecosystem to function may vary greatly from region to region. In fact, we know of no single subset of species that on their own would serve to operate all ecosystems and provide all ecosystem services in all regions of the planet. Therefore, diversity in a given location may increase productivity and ecosystem functions in that location, whereas diversity at the regional or global level is actually necessary for the operation of important ecosystems in all geographic regions. Although individual species may possibly be redundant in some locations, it is possible that on the global scale few if any are really redundant. A clear statement on this topic is given by Chapin *et al.* (1997, p. 505):

The abundance of species with similar ecological effects should give stability (resistance and resilience) to ecosystems in the face of increasingly rapid human-induced environmental change. Loss of a keystone species or of all species in a major functional group will, by definition, have large ecosystem effects. Efforts to identify and protect such species and groups often yield demonstrable near-term benefits. Of increasing concern is the loss of species that have similar ecosystem effects but differ in their environmental responses. Loss of such species may reduce ecosystem resilience and the capacity to adjust to ever-increasing rates of environmental change. This latter role of diversity is not adequately represented in current international conventions, but it may be one of the most important mechanisms by which we sustain the long-term functioning of ecosystems and the services they provide to society.

Biodiversity and Markets

Returning to the economic questions, to what extent can we hope to commercialize these contributions of biodiversity? Obviously, they are economically important, but can the

market capture them? Can the economic contributions of biodiversity be used to generate incomes to the owners of biodiversity that will provide them with incentives to conserve it? Can they make conserving tropical forests more attractive than clearing them? This is a critical question: Forest owners do not conserve forest because they are important to humanity. Rather, if they conserve them, they do so because they can profit from so doing. Therefore, we need to know whether the important services provided by biodiversity can be the basis for profits from forest conservation or for conservation of sources of biodiversity more generally. In this context, I again examine the categories under which I classified the contributions of biodiversity:

- Increasing productivity
- Providing insurance
- Providing knowledge
- Maintaining ecosystem services

One of the most fundamental insights into the operation of a competitive market economy is that under certain conditions it will align individual and social interests and provide incentives that lead to an efficient outcome. In the famous words of Adam Smith in his *An Enquiry into the Nature and Causes of the Wealth of Nations* (1777),

Every individual ... neither intends to promote the public interest, nor knows how much he is promoting it. He intends only his own security, his own gain. And he is in this led by an invisible hand to promote an end which was no part of his intention. By pursuing his own interest he frequently promotes that of society more effectively than when he really intends to promote it.

This is a beautiful metaphor: Market forces are an invisible hand, steering us to act in the interests of society as a whole when in fact we only seek to promote our own interests. Recently, this insight was formalized and made more precise via some important propositions from economic theory, including the First Theorem of Welfare Economics. These propositions state that if all goods are private goods (i.e., there are no public goods) and the private and social costs of all activities are equal, then a competitive market economy is Pareto efficient (i.e., operates so as to leave unexploited no possibilities for mutual gain). This is a remarkable result and provides the basis for economists' belief in the efficacy of market systems and the desirability of market-based approaches to economic organization. However, in the context of biodiversity the restriction that all goods be private is critical.

What is the public-private good distinction? A public good is one that has two properties: My consumption does not interfere with yours, and the provider cannot prevent non-payers from benefiting from the good. Such goods are said to be nonrival and nonexcludable, in contrast with private goods, which are both rival and excludable. A seat at the opera is a private good: If I sit in it you cannot, and the management can certainly exclude nonpayers from seeing the performance. Law and order, in contrast, is a public good: It benefits everyone in the region in which it is enforced and the benefits cannot be restricted to those who have contributed to its costs.

Markets are not good at providing public goods: Their nonexcludability makes it difficult for the provider to earn a good return on the costs of providing them. Knowledge is an interesting and relevant example: It is naturally a public good because it can be passed costlessly from one person to another and enjoyed by all of them, even though none of them, or perhaps only the first, paid for it. Hence the existence of intellectual property rights, instituted as a means of ensuring some return on the generation of knowledge. Because of the difficulty in appropriating the returns on their provision, markets tend to underprovide public goods relative to an economist's concept of what is efficient for society. Consequently, they have traditionally been provided by the public sector. Some of the services provided by biodiversity are public goods, although biodiversity does not fit the traditional mold for public goods completely. The extent of biodiversity is not something that can be determined by the public sector because it is the result of literally billions of land-use choices throughout the world. It is also strongly influenced by issues such as climate change, which are again driven by billions of heating and transportation choices. In fact, biodiversity has been called a privately produced public good. For the remainder of this argument, the key point is that the First Theorem fails in the context of public goods, and indeed it has long been recognized that markets will underprovide public goods relative to the level that would be required for efficiency.

One further basic economic point is needed—a familiarity with the diamond–water paradox and the limitations of market prices as indicators of “importance” to society. Discussion of this paradox helps us to be clear that the price of a good does not reflect its importance in any overall social or philosophical sense. Very unimportant goods can be valued more highly by the market than (have higher prices than) very important goods. The classic illustration of this is the diamonds and water paradox, which perplexed economists through the eighteenth and nineteenth centuries until its resolution by Alfred Marshall. The point here is that water is clearly more important to human society than diamonds, but diamonds trade in the market at prices far in excess of those fetched by water. Why? Marshall's answer was simple and is now part of common knowledge: Price is set by supply and demand. The market price is the price at which the amount supplied is also the amount demanded. In the case of water, the supply (at least in Marshall's time) was so large as to exceed the amount that could possibly be demanded at any price. Consequently, the price was zero: Water was free. Now, of course, the demand for water has increased greatly as a result of population growth and increasing prosperity, whereas the supply has remained approximately constant so that water is no longer free. For diamonds, being naturally scarce, the desire for ownership always exceeded that which could be accommodated naturally. The market price was high as a result of competition between rich people for the few diamonds available.

What are the implications for biodiversity? Simply that even if it is of great importance to society, and is not a public good, it will not necessarily be possible to convert this importance into value in the market place. The balance of supply and demand will be critical here, as shall be shown in the

context of the commercialization of the genetic knowledge inherent in biodiversity.

Productivity

To the extent that diversity increases productivity in agricultural systems, we would expect that farmers would be willing to pay for it. Arable farmers achieve some of the benefits of diversity by crop rotation, i.e., rotating between a series of different crops in successive years. The different crop types make different demands on the soil and contribute different nutrients to it. However, the range of crops used for this purpose is quite limited and does not contribute in any substantial way to the conservation of biodiversity. The other mechanism through which diversity contributes to productivity in agriculture is via its contribution to the breeding of new plant species that are better adapted to emerging conditions or more resistant to new diseases. At this point, the productivity and knowledge roles of biodiversity merge, and I comment on the possibility of commercializing the knowledge role later. These comments on biodiversity's contribution to knowledge will also apply to the contribution that biodiversity makes to human societies via the breeding of new varieties.

There appears to be some appreciation of the benefits of diversity in tropical agriculture, in which there is a tendency to grow several crops together or to grow crops in a way that conserves the original forest. Traditionally, coffee was grown as an understory plant beneath high tropical forest trees: This benefits the coffee, which is a shade-tolerant plant, takes full advantage of the light available in the region, and avoids the need to destroy the main forest trees to make land available for coffee growing. This practice also allowed other commercial crops to be grown with the coffee, such as citrus fruits and avocados, thus allowing farmers to diversify their risks. In cases such as this there is a contribution to the preservation of diversity because of the conservation of the forest. Studies have shown that forests converted for production of shade-grown coffee retain a very large proportion of their original biodiversity and that growing in this way is less expensive per pound produced than plantation growing. This cost difference reflects in part the greater productivity of diverse ecosystems and the more effective cycling of nutrients in these plant communities (the total yield of coffee per hectare, however, is less; *Perfecto et al.*, 1996). In this case, it seems that there can be some conditions under which the productivity enhancements of diverse systems can be realized commercially, with attendant benefits for biodiversity conservation.

Insurance

Insurance is clearly something for which there is a demand. Most of us insure our homes and our cars and have health insurance. Therefore, perhaps the insurance role of biodiversity is one for which people will pay. The difficulty here is that until recently this insurance has been provided as a public good—indeed, as a global public good. Consider in the light of the public–private good distinction the conservation of rice varieties by the IRRI mentioned previously and in particular

the use of one of these to provide a defense against the grassy stunt virus. In cases such as this, the insurance was provided as a public good. It was available to all for the cost of buying the new variety of rice incorporating resistance to the grassy stunt virus. You did not have to pay an insurance premium to benefit from the insurance. The developers of the new variety could not exclude from using it those who did not contribute to its development by paying insurance premiums.

At this point, I again digress briefly into economics. Risk, such as the risk of the destruction of a part of a crop, is managed in a market system by contingent contracts. A contingent contract is a contract that pays a specified amount if and only if a specified contingency occurs. Buying the contract reduces the risk to you that is associated with the specified event. If it occurs and has negative consequences, then you are to some degree compensated by the payment made to you under the contract. An insurance contract is a classic example of a contingent contract: You buy it by paying a premium and it entitles you to a payment if and only if a specified event—the insured peril—occurs. It is crucial for the efficient management of risks that the payment through which one purchases a contingent contract should not be contingent. You pay the insurance premium whether you use the insurance or not: The only uncertainty or contingency is whether you can make a claim under the policy.

It follows that the problem of the public good nature of the insurance provided by the existence of new varieties could not be overcome by charging premium prices for them. This price would only be paid after the product had been developed and needed. If the new variety were never needed, then this price premium would never be paid. No contingent contract is being sold in this framework.

There is a possibility that the public good nature of the insurance will change. Public goods can become private goods through either institutional or technical change. A good example is television broadcasting. Until about 10 years ago, this was a public good par excellence: A broadcaster could not exclude from viewing a program anyone in the reception area so that the non-excludability property of public goods held, and of course there is no rivalry in consumption. My viewing a TV broadcast in no way interferes with your viewing. The development of scramblers changed this. A TV broadcast can now be scrambled so that it can only be viewed by those who have purchased a descrambler. Broadcasters can now exclude those who have not paid from viewing their programs, which are therefore no longer public goods. A public good has been privatized.

Developments in the area of intellectual property rights for agricultural biotechnology could change the situation in a similar way for the insurance value of biodiversity. These may lead to the privatization of a hitherto public good. Crop developers are increasingly patenting genes developed to enhance the properties of crops, including such properties as their taste, productivity, and insect resistance. Most agricultural biotechnology companies have a large and growing portfolio of patents on genes and on genetically modified plant varieties. They are also aggressively defending these patents, to the extent of developing and introducing “terminator genes” that will ensure that the properties conveyed by patented genes will not be transferred to offspring of the plant. Consequently,

users cannot breed from seed that they have bought but must purchase more from the supplier. It is possible that plant breeders with such a tight hold on their intellectual property will be able to extract from users a great enough return to justify substantial investment in biodiversity conservation. The aggressive enforcement of intellectual property rights might act here like scramblers did with TV broadcasts, effectively privatizing a previously public good. Were it to happen, this would increase substantially the incentives for biodiversity conservation, but possibly at the cost of restricting access to the latest agricultural technology to those with the ability to pay a premium.

There is already a good illustration of the possible side effects of privatization of genetic knowledge. The bacteria *Bacillus thuringiensis* (*Bt*) produces a toxin that kills many crop pests and is itself biodegradable. For this reason, organic farmers use it as a pesticide: Because it is biodegradable it leaves no dangerous residues on the crops on which it is used. Monsanto and Novartis recently incorporated genes from *Bt* into transgenic crops. The presence of these genes in the plants means that the plants benefit from the defense provided by the *Bt* bacteria, which is the production of proteins that are toxic to the main pests of cotton and corn. Because the *Bt* genetic defense against pesticides is now widely used, it is possible that pests will develop resistance to it. Resistance develops faster the more widely a defense is used. Therefore, within a few years there may be generations of crop pests that are immune to this way of defending crops, i.e., immune to the *Bt* toxin. Monsanto and Novartis will seek to develop variants on the *Bt* genes, and with their scientific and financial resources they may succeed. If so, they will sell a new generation of transgenic plants with defenses against the new generation of pests. However, these will be their proprietary products, covered by their patents. Because of the development of resistance to the *Bt* toxin, organic farmers will no longer be able to use *Bt* as a harmless pesticide. They will be forced to buy proprietary defenses against pests. This is a clear illustration of the two factors mentioned previously: development of intellectual property rights in genetic knowledge leading to both stronger incentives to conserve and to develop further and also leading to a restriction of access. In the case of transgenic crops including the *Bt* defenses, Monsanto recently announced that all growers of *Bt* corn will be required to grow plots of nonengineered corn that are at least 20% of the size of the engineered crops. The aim here is to provide sufficient nonengineered corn that the development of resistant pests will be delayed or possibly even prevented. (“Monsanto concession”, 1999).

Knowledge

Here, I discuss the role of biodiversity as a source of knowledge. There are two different areas of application here: the development of medical products by the pharmaceutical industry and the development of new or better crops by the agricultural biotechnology industry.

In applications of biodiversity to the development of pharmaceuticals there has already been some progress toward commercialization. Recognition of the likelihood that tropical plants contain chemicals that could be forerunners of

pharmaceuticals has led most major drug companies to pursue bioprospecting as a way of finding new pharmacologically active substances to serve as a basis for drug development. Typically, they have sought these compounds in the tropics, in areas where there is extensive interspecies competition, or in other extreme areas. They have been willing to pay quite substantial sums for access to these regions, and they have made deals with host countries that involve giving them a royalty on the products that might eventually be based on their prospecting. Such royalties could be large relative to the incomes of the countries concerned. Merck, Inc., one of the largest pharmaceutical companies in the United States, has an agreement with a Costa Rican agency called InBio (Instituto Nacional de La Biodiversidad) for bioprospecting rights in Costa Rica. The terms of the agreement are that Merck paid InBio a fixed sum, \$1.35 million, to be used for forest conservation in exchange for the right to receive samples collected by InBio and to use these as the basis for new product development. Should any of them prove commercially successful, Merck will pay InBio a royalty on the revenues generated. Similar agreements are in place between other U.S. pharmaceutical companies and regions of Central and South America.

The discovery of the PCR enzyme and the agreement between Merck and InBio and several other drug discoveries based on plants from developing countries led to a wave of optimism, perhaps excessive, about the potential commercial value of *in situ* biodiversity in developing countries. What in fact is the commercial potential here? There is no question that pharmaceutical and agricultural products of great human and commercial value have been and will in the future be developed from the biodiversity in tropical countries. The key question is how much of this will be returned as a reward for the conservation of the originating biodiversity. In answering this question, one must take note of several points. The first point is related to the discussion of the diamond-water paradox: Not everything that is important will have value in the marketplace because there is nothing associated with being important that rules out the possibility that the supply may exceed the demand. Some commentators have seen this as a critical issue in the market for biodiversity-based genetic information. There are literally millions of organisms in the world that might provide genetic information, and if we do not know which ones will provide valuable information and which will not, then the supply of potential genetic leads is huge, possibly greater than pharmaceutical companies can process. In such a situation, the market price for such leads would be near zero. However, recent calculations suggest that in a small number of the world's biodiversity hot spots, bioprospecting rights may be worth as much as \$9000 per hectare. This is small in relation to the amount that might ultimately be derived from drug sales but still large relative to other uses of the land. In fact, it is approximately a century's worth of ranching income (Rausser and Small, 1998). The key insight in these calculations is that prior knowledge of the nature of the ecosystems in a location can improve estimates of the probability of finding commercially interesting compounds there and can suggest where search would be profitable and where success is unlikely. In this case, not all organisms or all leads are

equivalent: Some have much greater chances of success than others. Prior scientific information can change the odds of success from one 1 in 10,000 to approximately an order of magnitude better. In practical terms, this means that developing countries can clarify the commercial attractions of their biodiversity by performing research on the ecosystems of which it is a part. This is similar to a country with potential oil reserves engaging in basic geological prospecting before seeking to negotiate leases for oil development. The results may be positive or negative, but either way they will give the country a better view of its prospects. In those cases in which the research is positive, the impact on the value of prospecting rights could be large.

Another important point is that an immense amount of human skill and expertise are needed to develop a plant specimen into a commercial drug. Typically, there will be a minimum of 10 or more years of work by hundreds of skilled people working with millions of dollars of sophisticated equipment. Unfortunately, very few plant extracts actually produce drug leads (i.e., contain pharmacologically active compounds with no obvious ill effects)—probably less than 1 in 10,000. Of these few, very few become commercial drugs—less than 1 in 100. On average, perhaps 1 in 250,000 samples collected leads to a commercial drug. (“When Rhetoric Hits Reality,” 1998).

Therefore, the chance of any individual bioprospecting operation leading to a commercially valuable drug is very small indeed. Also, even if it does produce a drug, tens or even hundreds of millions of dollars will have to be invested, with significant chances of failure. Developments in biotechnology are currently altering this picture. They are reducing the time needed for testing and development and giving greater insights into the kinds of chemicals likely to be successful. By reducing the costs of drug development based on bioprospecting, they are making bioprospecting more attractive. For example, the cost of screening 10,000 samples for pharmaceutical potential 10 years ago would have been \$6 million: Today it is \$150,000 (Reid *et al.*, 1993). Simultaneously, advances in knowledge are also making more effective alternative methods of drug development, based on understanding of the cellular and genetic mechanisms of disease. In total, the picture that emerges is one of heavily guarded optimism. Bioprospecting does have economic value, and technological developments may be increasing that value. However, in the short term we cannot expect great sums of money to flow to the conservation of biological diversity because of bioprospecting possibilities.

There is another problem to be overcome in establishing an income flow from bioprospecting—a problem with intellectual property rights. The same plant may occur in several different regions, and the same or similar chemicals may occur in different plants. Therefore, the same or similar drugs may be derived by different routes from different plants or different geographic regions. Research toward a commercial product has to be well under way before it is patentable; therefore, there is always a risk of being blocked by a prior patent.

There is also a risk, regarding the conservation of biodiversity, that biodiversity is valuable but leads to no direct

commercial application. In a recent article on the value of marine bioprospecting, Carte (1996, p. 284) stated,

Although many of these products are not likely to become therapeutics, the information gained from studying them is likely to lead to the development and understanding of novel molecular targets, which may in turn lead to the development of new therapeutic agents.

This is a classic statement of the importance of basic knowledge. Basic knowledge is a public good: Its importance is great but it is not patentable and not something that can be appropriated by a typical bioprospecting contract with an element of royalty payment or revenue sharing. The development of basic knowledge is typically publicly funded precisely because its economic benefits, although potentially immense, are difficult to appropriate. More constructive thinking about how to realize the undoubted importance of bioprospecting in terms of income for conservation is needed. A further illustration of this point is provided by the example of taxol mentioned earlier. Taxol is a promising anti-tumor agent in breast and ovarian cancers that can be extracted from a fungus that lives in the phloem (inner bark) of the Pacific yew tree. Taxol was first isolated from the tree itself, but the tree is relatively rare and slow growing, and it produces little taxol; therefore, a search for other sources was initiated (Stierle *et al.*, 1993). Ultimately, little in the way of economic returns may flow to the regions in which taxol was discovered.

Biodiversity can also be applied to the development of new or better crops: To date, this has probably been the most important commercial application of biodiversity. As noted previously, the existence of a pool of genetic variation provides plant and animal breeders with the raw materials for developing new varieties and more productive or resilient variants of existing varieties. The existing varieties of a commercially important crop are usually the property of a commercial firm or of a research facility and are protected by patents. For example, the University of California owns the patents of many varieties of strawberries. These patents cover varieties that are best suited to different soil types and different weather conditions, that are least prone to spoiling during transport and storage, and so on. For most other commercial crops, the varieties are owned by seed companies, whose main asset is often the intellectual property represented by their ownership of patents to widely used varieties. In this context, the market can certainly recognize the value of biodiversity, provided that it is of the type that seems likely to contribute to the development and refinement of commercially important crops. Unusual variants of commercial crops, such as early variants of wheat, corn, or soybeans, would qualify, and possibly so too would their near genetic relatives. However, biodiversity more broadly would probably not derive a value through this process, even though genes from unrelated plants might enhance the commercial potential of existing crops.

Ecosystem Services

Perhaps the most promising approach is to consider selling the services of natural ecosystems and using the revenue to provide incentives for conserving the biodiversity that

supports them. Selling services provided by natural ecosystems can potentially provide incentives for the conservation of these systems and thus indirectly of biodiversity. For example, watersheds provide economically valuable services for which there is a market, and indeed recognition of this has already led to the conservation of significant forest areas (Chichilnisky and Heal, 1998). Some commentators (Reid, 1998) have suggested that as much as 15% of the earth's land area serves as watersheds for large cities and so could legitimately be conserved on the basis of the watershed services that it supplies. Many of these watersheds are areas of considerable biological uniqueness and their conservation would be a major advance for the conservation of biodiversity. Their functioning as watersheds probably depends substantially on the continuation of their current levels of biodiversity.

Ecotourism is based on the preservation of intact ecosystems and the more appealing elements of biodiversity to be found in some of these systems, and revenues from this are providing powerful incentives for the conservation of several important ecosystems (Chichilnisky and Heal, 1998; Heal, 2000a). Insofar as ecotourism conserves tropical ecosystems, it contributes to the conservation of biodiversity. In certain regions, particularly southern Africa, ecotourism is making a major contribution to the conservation of biodiversity. In Angola, Botswana, Kenya, Malawi, Mozambique, Namibia, South Africa, Tanzania, Zambia, and Zimbabwe, approximately 18% of the total land area is now devoted to the support of wildlife. This is both a significant amount in total and a massive increase relative to 15 or 20 years ago (Bond, 1993; Cumming, 1990a, and b; Cumming and Bond, 1991). This has led to an increase in the populations of several previously endangered species and to more robust breeding populations of many important birds and mammals. All of this has been driven by the fact that in many parts of this region land devoted to ecotourism and sport hunting can earn a higher return than land devoted to more conventional agriculture. Figure 2 illustrates these phenomena: It shows for Zimbabwe both the growth increase in land whose primary use is the support of wildlife and the favorable economic returns to wildlife conservation relative to agriculture in parts of the region. (Regions III–V are either arid regions or wetlands.) Although the growth of ecotourism as an economically important activity has increased most in southern Africa, this region is not unique in being able to generate conservation incentives by tourism. Central and South America, and parts of Asia, are now benefiting from ecotourism, which is providing significant returns to the conservation of certain endangered species in these regions (Heal, 2000b; Freese, 1999; Honey, 1999).

Finally, there is a real prospect of commercializing some of the carbon sequestration services of forests under the terms of the Kyoto Protocol, which provides for compensation for some carbon sequestration activities via its provisions for joint implementation and through its clean development mechanism. I have estimated elsewhere (Heal, 2000b) that this could generate an income as high as \$50–100 per hectare per year, which is high enough to radically change the incentives for forest conservation and hence biodiversity conservation.

There are also other economic mechanisms through which the goods and services provided by tropical forests and their

Figure 2 (A) Financial returns to wildlife and cattle ranching in Zimbabwe. (B) Returns per hectare from cattle and wildlife in Zimbabwe. (C) Land area (square kilometers) for wildlife conservation in Zimbabwe.

associated diversity might be marketed, although it is not clear whether these mechanisms can be applied generally. One is the sale of "nontimber forest products," which are commercially valuable forest products that are not produced by

tree cutting. They are therefore not timber, and their harvest and sale are compatible with conservation of the forest. They include various tropical fruits, vines that can be used as ropes, rattan (which grows among the trees), resins such as latex, and plants used as medicine by local populations. This last use is important. Approximately 4 billion people have no access to Western-style medicine and in times of sickness depend on plant extracts; this is known as ayurvedic medicine. This market is important in human terms, and although the amounts of money involved are small by comparison with those in Western medicine, they could still be enough to provide a significant incentive. Recent estimates suggest that in some tropical forests the collection and sale of nontimber forest products could yield as much as \$60–140 per hectare per year, although many other studies have suggested significantly lower numbers (Grimes *et al.*, 1994; Houghton and Mendelsohn, 1996; Peters *et al.*, 1989). These are significant amounts. Given that they are sustainable, i.e., can be earned year after year, they are probably sufficient to justify conservation of forests even in the face of pressure for logging. However, currently there are a limited number of studies on this form of forest use so that the generalizability of these numbers is not clear, and whether the implied levels of harvesting are truly sustainable is also unclear.

The different mechanisms for generating income from natural ecosystems and the biodiversity that powers them are not mutually exclusive: The same land area could earn income by all mechanisms. A forest could obtain returns from carbon sequestration, bio-prospecting, nontimber products, managing a watershed, and ecotourism. In fact, the region of the Mata Atlantica (Brazilian coastal rain forest) inland from Rio de Janeiro is in a position to do exactly this. It manages the watershed for Rio in much the way that the Catskills region does for New York. It also manages the stream flow of the river Rio Paraibo do Sul, which provides most of the electric power for Rio via hydropower. These two services make it truly a major utility for Rio, with great economic value. Additionally, it supports a wide range of endemic species, sequesters carbon, and acts as a magnet for tourists. Currently, the region obtains a financial return only on one of these activities—ecotourism. In a case such as this, it is clear that the economic incentives for conservation could be immense, if we were only to do effectively what we already know how to do.³

Conclusions

What can we conclude about biodiversity, its economic importance, and the prospects for generating income based on this? Clearly, its importance is great, in the sense that it has been and remains a key contributor to human well-being. We understand enough of this contribution for its magnitude to

³All of these measures are consistent with the United Nations Convention on Biological Diversity, to which many nations (although not the United States) have subscribed. This states in article 11 that "Each Contracting Party shall, as far as possible and appropriate, adopt economically sound measures that act as incentives for the conservation and sustainable use of biological diversity".

be clear, although there are probably many aspects that are still unknown to us. Economically, the following is a key question: Can this importance be reflected in a commensurate income yielded by the conservation and use of biodiversity and of goods and services based on it?

In essence, much of what biodiversity contributes is, or has traditionally been, a public good. Its contribution to the functioning of natural ecosystems is nonexcludable and nonrival, as is its insurance value. Also, knowledge is the quintessential public good. Despite the overwhelming publicness of much that biodiversity offers, there is some prospect of commercializing a limited part. Some of the services provided by natural ecosystems can be privatized and sold, generating a return to the conservation of the biodiversity that supports them. In the case of knowledge, the prospect of commercialization rests on the ability to establish intellectual property rights that will effectively privatize some of the public good aspects of its insurance and knowledge functions. Probably the most fundamental of these functions, like basic scientific research and development, will never be privatized and will thrive only with financial support via other mechanisms.

In summary, biodiversity is important economically. There are some market-based approaches to obtaining returns from biodiversity that can provide incentives for its conservation. If fully implemented, they would have a profound and positive impact. However, they would not solve the problem of biodiversity conservation. They would need to be supplemented by non-market measures such as the Endangered Species Act (ESA), the Convention on International Trade in Endangered Species (CITES), the Marine Mammals Protection Act, the Fishery Conservation and Management Act, and others. I am not suggesting that these are good examples of nonmarket policies: Indeed, in several cases they are not. The point is that they illustrate the type of option available as an alternative to the market. Of course, except for CITES, the previously listed measures are all domestic U.S. measures. To be really effective, we would need global equivalents—a Global Endangered Species Act, for example. Given the political complexity of the domestic ESA, this prospect should illustrate clearly the desirability of market-based policies whenever possible.

It is important to note that even regulatory approaches such as the ESA can give rise to market-based incentives if coupled with provisions for measures such as mitigation banking. In the case of the ESA, several states have modified this in a way that has proven highly effective and has introduced economic incentives where none existed in the initial formulation of the act. A good illustration is an agreement reached between the International Paper Corporation and the U.S. Fish and Wildlife Service concerning the red cockaded woodpecker. This bird is endangered and nests in forests owned by International Paper. The U.S. Fish and Wildlife Service and International Paper reached the following arrangement: A target number of breeding woodpecker pairs was agreed on, and provided that this number is attained or exceeded, then International Paper will be regarded as complying with the ESA, whatever modifications it might make in the habitat under its control. Furthermore, the agreement also provided that any surplus of breeding pairs over this number could be “banked.” This means that it could be used by the

company to offset ESA requirements with respect to red cockaded woodpeckers elsewhere, or title to the surplus could be sold to other landowners and used by them to gain some measure of exemption (Jorling, 2000; Noss *et al.*, 1997). The important point is that the costs of compliance with the ESA have been reduced by this agreement, without reducing its effectiveness. Indeed, there are additional benefits: Because the production of nesting pairs over a target level is saleable, International Paper now actually has an economic incentive to encourage the endangered species, something it never had with a strict interpretation of the ESA. Recent reports suggest that International Paper may be able to sell banked breeding pairs for as much as \$100,000 per pair (W. Coleman, personal communication). Similar mitigation banking systems have been put in place for wetlands, which have to be conserved under the Clean Water Act and which also provide important habitat for endangered or threatened species.

In the cases of the red cockaded woodpecker and wetlands, regulation has produced a market. The market occurs as a result of efforts to meet the regulations at minimum costs and has the positive effect of providing stronger incentives than the original regulation for the conservation of the endangered species or habitat. In principle, we do not need to go through the process of regulation to set up a market. The most obvious move from an economic perspective is instead to create a market in situations in which this seems needed by using the state as a buyer. In other words, in the case of the red cockaded woodpecker, the government could just pay landowners on whose land the woodpeckers breed. This immediately establishes an incentive for conservation without the political and other costs of regulation. Systems of this type are currently being used on a trial basis in parts of the United Kingdom. In regions in which hill farming is economically marginal, and has been subsidized by the European Community's Common Agricultural Policy, the farming subsidies have been replaced by subsidies for preserving the ecological integrity of the countryside.⁴ Specifically, farmers are paid to grow and maintain hedgerows, ponds, wetlands, wildflowers, and coppices that provide habitat for birds and mammals. The *Financial Times*, the European equivalent of the *Wall Street Journal*, recently commented in an editorial that in many cases it would make more economic sense to pay farmers to provide “ecological sustenance” rather than to grow food that is clearly surplus to the region's needs and cannot compete on world markets (“Too much food,” 1998). This solution is less attractive than establishing a market in which consumers buy directly, as in the cases of ecotourism or watersheds, because the money spent by the government has to be raised as tax revenue from individuals or corporations. This can produce a loss of economic efficiency elsewhere in the economy. However, if the services provided by biodiversity are public goods, then there may be little alternative to having the public sector act as a buyer on behalf of society as a whole.

Glossary

Ecosystem services Goods and services provided by nature that contribute to human well-being such as clean water and charismatic wildlife.

Efficiency In economics, efficiency may refer to Pareto efficiency, which occurs when making one person better off necessarily makes someone else worse off. Efficiency may also refer to Kaldor–Hicks (or potential Pareto) efficiency, which occurs when those who are made better off by a change could not fully compensate those who are made worse off by that change. Efficiency implies that society cannot improve unambiguously on its current use of resources; it says nothing about distributional equity.

Externalities Costs or benefits of an action taken by one party that directly impact the welfare of other parties that are not reflected by market prices.

First fundamental theorem of welfare

economics Mathematical proof that if competitive markets exist for all goods and there are no externalities or other market imperfections, then the market system leads to a Pareto-efficient outcome.

Public goods Goods whose consumption is nonrival and nonexcludable. Nonrival means that one person's consuming it does not preclude another from doing likewise. Nonexcludable means that the provider of the goods cannot ensure that only those who have paid can benefit from its provision. A fireworks display is an example of a public good.

Risk Situation in which outcomes are stochastic (not deterministic) but each alternative has a known probability of occurrence. Risk may be idiosyncratic (specific to an individual) or systemic (shared).

Introduction

Human actions have become important drivers of global change, including land-use change, changes in nutrient cycles and pollution, species declines and extinction from over-harvesting, and climate change, all of which can lead to significant biodiversity loss. Although biodiversity loss may be viewed as a loss in its own right (intrinsic value), it can also have serious negative consequences on human well-being. Humans depend on biodiversity to produce ecosystem goods and services, ranging from foods, fuels, fibers, and medicines to ecosystem functions that provide water purification, soil enrichment, nutrient retention, and climate regulation.

This entry discusses two important and related topics. First, what are the various types of benefits that biodiversity provides to humans? These benefits can either directly affect human well-being through harvesting or other activities or indirectly benefit people through the role biodiversity plays in supporting ecosystem functions that lead to the provision of ecosystem services. The sources of benefits might come from components of biodiversity (i.e., individual species) or from the complex interactions among biotic and abiotic elements of ecosystems. Second, what is the potential for markets to provide incentives for the conservation of biodiversity? Market forces often lead to the loss of biodiversity. However, when biodiversity conservation is important for human well-being, there is the potential for appropriately designed market mechanisms to maintain or enhance biodiversity through payments that reflect value to ensure the continued supply of benefits.

Direct and Indirect Value

Some components of biodiversity are valuable because they contribute directly to human well-being. People value particular

plants and animals because they provide nutritious food or medicines. People may also value particular plants and animals because they have spiritual or symbolic value. Changes in other components of biodiversity, such as the abundance of soil microorganisms, do not have a direct impact on human well-being.

Many things that people do not value directly, however, still have value. Intermediate goods and services are inputs into the provision of final goods and services that people directly value. Soil microorganisms have value because they are essential for plant growth and without which there would be no agricultural crops. The interactions of organisms in a system ultimately determine the provision of ecosystem services that humans directly value. Thus, nearly all components of biodiversity are likely to have at least indirect value because of the role they play in determining the functioning of ecosystems that support the provision of final ecosystem services that have direct value to people.

An analogy can be made between biodiversity and economic infrastructure. Most people do not care directly about infrastructure, but deterioration of infrastructure will cause declines in the provision of final goods and services. Just as ball bearings indirectly contribute to well-being because they are important intermediate goods, soil microorganisms and other components of biodiversity are important components in the production of ecosystem services on which society depends. Ideally, the indirect and direct value of biodiversity would be reflected in markets so that society could be assured that economic activity took proper account of the costs and benefits of degrading or enhancing biodiversity. As will be discussed, however, this is not always the case.

Economic valuation methods are well suited for capturing the values of final goods and services. However, much of the value of biodiversity comes indirectly through the complex interactions among sets of organisms or functional groups

that collectively determine ecosystem functions that lead to provision of ecosystem services. It is more difficult to use economic valuation methods to uncover the indirect value of biodiversity. Valuing the contributions of biodiversity to the provision of ecosystem services requires understanding not only the value of final goods and services but also the ecological role that biodiversity plays in the provision of these goods and services. Only integrated ecological and economic analysis can uncover the indirect value of biodiversity.

The Contributions of Biodiversity to Human Well-Being

Commodity Production and Ecosystem Services

Biodiversity plays an important direct role in the production of commodities, such as agricultural crops, timber, and fish. Here it is the particular species (e.g., maize and bluefin tuna) that have value. This type of value is often readily observable because harvesting these species yields marketed commodities with explicit prices. These prices also reflect the indirect value of biodiversity. In addition, biodiversity plays an important indirect role in determining ecosystem functions on which valuable ecosystem services, such as the bluefin tuna fishery, depend.

If species diversity promotes ecosystem function and this enhances the production of ecosystem goods and services, then species diversity provides a significant indirect benefit to society. A number of experimental studies, primarily but not exclusively in grassland ecosystems, have found a causal relationship between species richness and ecosystem function. Although some early results led to questions regarding the extent to which the apparent relationship could be explained instead as a statistical inevitability of having more species (see Grime, 1997), more recent work demonstrates functional effects of species diversity beyond those expected from selection effect or portfolio effects (Tilman *et al.*, 2001). Although a debate persists regarding the relative importance of these effects, evidence suggests that biodiversity improves human well-being through contributions to ecosystem function that underpin ecosystem services.

On the face of things, biodiversity and the production of agricultural commodities appear to be at odds. Monoculture agriculture is the antithesis of diversity. All else equal, greater diversity appears to mean less of the most valuable species, and it may also preclude economies of scale in production. However, evidence from experimental plots has demonstrated “transgressive overyielding,” the production of biomass at higher levels of biodiversity in excess of yields from the best-performing monoculture (Nyfeler *et al.*, 2009). These effects appear to be the results of important ecological interactions among species and to increase over time (Allen *et al.*, 2011; Cardinale *et al.*, 2007; Fornara and Tilman, 2008; Nyfeler *et al.*, 2009; Tilman *et al.*, 2001, 2006).

Studies have yet to demonstrate transgressive economic overyielding (i.e., superior profitability). For increases in biomass to translate into increases in value of production, the percentage increase in quantity must exceed the percentage decrease in average value per unit of biomass, net of harvest

costs. Research to date leaves open the possibility that more diverse systems could generate larger returns for agricultural commodities, timber, or fish. Much less is known about the diversity–function relationship in forest and marine systems due to the logistical difficulties of establishing rigorous controlled experiments in such systems.

In the same way that biodiversity has been shown to increase the production of biomass, it may also enhance other ecosystem functions with implications for human well-being. The more “functional contexts” considered, the greater the number of species that appear to play important roles in ecosystem service provision (Isbell *et al.*, 2011), which itself suggests an indirect value for biodiversity. However, increased ecosystem function does not necessarily mean increased quantity or value of ecosystem services. Only a subset of the components or characteristics of a system will be affected by changes in function, and only a subset of these provide direct benefits to society.

Such caveats notwithstanding, biodiversity does appear to be important to ecosystem services. Enhanced biodiversity has been shown to lead to greater soil carbon storage (Fornara and Tilman, 2008; Tilman *et al.*, 2006), which helps to mitigate the release of carbon dioxide to the atmosphere. Greater species diversity has also been shown to increase nitrogen uptake (Fornara and Tilman, 2008; Reich *et al.*, 2001; Tilman *et al.*, 1996), reducing the flow of nitrogen pollutants to water bodies.

Risk and Insurance Benefits

Beyond the possibility of direct and indirect contributions to mean levels of commodity production and other ecosystem services, biodiversity may also reduce the dispersion of returns over time. In experimental plots, diversity has been shown to increase ecosystem stability and decrease the variability of yields more so than an equivalent portfolio of monocultures (Tilman *et al.*, 2006). Biodiversity can also be an important factor over the longer term by maintaining varieties or species better suited to stochastic future conditions (Brock and Xepadadeas, 2003). By reducing risk – for instance, risk associated with weather fluctuations, pests, and pathogens in an agricultural setting – biodiversity contributes an insurance value to society (Perrings *et al.*, 2009). For individual farmers, whether the value of mitigating risks specific to them (i.e., idiosyncratic risk) via enhancing biodiversity is worthwhile depends on costs in terms of reduction in expected returns and the availability of traditional insurance. Even in cases of systemic risk, for which markets do not provide insurance, the stability-enhancing benefits of biodiversity may or may not outweigh the costs of increasing diversity.

Uncertainty, Irreversibility, and the Benefit of Options

Biodiversity provides benefits to society in the face of uncertainty, where the probabilities of certain outcomes are unknown, as well as in the face of risk, where probabilities can be assessed. We have uncertainty, for example, over ecosystem conditions in 2100 or beyond given global change and over the preference of future generations living in a changed

environment. Where the options available to future generations depend on continued existence of particular species, and where agricultural and land-use decisions can have irreversible effects on the continued existence of many species, biodiversity has an “option” value (Fisher and Hanemann, 1986). We would be willing to pay a certain amount of money today to retain the option of having the species in the future, even if it provides no instrumental value today and no certain instrumental value in the future.

Knowledge Benefits

We also have uncertainty over the benefits that undiscovered or unstudied species might bring. This uncertainty is perhaps most salient in the case of the knowledge benefits that such species might provide. Although knowledge benefits ultimately derive from particular species, uncertainty over which species will provide those benefits creates value for diversity *per se* (Polasky and Solow, 1995). Of particular interest has been the potential pharmaceutical value of compounds found in certain organisms, although the pharmaceutical value of the marginal species is likely to be quite small (Simpson *et al.*, 1996). In a similar vein, agronomists use knowledge of many different species to breed crop varieties with superior yield and/or resistance characteristics.

Biodiversity can also generate knowledge benefits in a variety of contexts in which engineers seek efficiencies through biomimicry, the emulation of the forms or processes that other organisms have evolved for “solving” problems. Biomimetic products under development include drag-reducing coating for marine vessels based on water fern, adhesive tape that mimics the hairy feet of insects, and artificial “leaves” capable of splitting hydrogen and oxygen from water molecules.

Esthetic, Spiritual, Cultural, and Recreational Benefits

Biodiversity directly contributes to human well-being in the form of esthetic, spiritual, cultural, and recreational benefits. People value “charismatic megafauna” (e.g., lions, tigers, and whales), and they value flora and fauna that defines regions in which they live or travel. A number of studies have shown that people are willing to pay more for property in more biodiverse areas. For example, Bark *et al.* (2009) find that the diversity of riparian vegetation increases nearby home values in Tucson, AZ, USA. This suggests that diversity, along with other characteristics of the riparian ecosystem, contribute indirectly to one or more amenities. That biodiversity contributes to human well-being is also evident in many recreational contexts. Ecotourism in places like the Great Barrier Reef and the Galapagos Islands are testament to the value that people place on biodiversity. To the extent that people value the chance to see particular rare or exotic species, biodiversity contributes indirectly to human well-being through the support of those individual species. However, there is also evidence that ecotourists value variety (diversity) *per se*. For instance, Naidoo and Adamowicz (2005) find ecotourists are willing to pay more to visit African rainforest reserves with higher avian species diversity, all else equal.

There is also considerable evidence that people value knowing that species exist even when they do not expect to observe them or directly benefit from them in any way (“existence value”).

Markets, Market Failure, and Policy for Biodiversity

Markets and Efficiency

Markets work by bringing together consumers who wish to buy goods and services with producers who wish to sell goods and services. Markets can be an effective way to provide information across a vast decentralized interconnected web of producers and consumers. Market prices provide signals to producers about how valuable the good or service is to consumers. Similarly, market prices provide signals to consumers about what it costs producers to provide the good or service. If the value of a good or service to consumers is greater than its cost to produce, there are potential gains from trade and a market price will provide an incentive for producers to supply the item to consumers. The first fundamental theorem of welfare economics states that when producers and consumers interact in competitive markets with full information and without externalities, the market outcome will be Pareto efficient, i.e., the only way to make one person better off comes at the cost of making someone else worse off.

When markets work well they provide incentives to produce goods and services at the lowest possible cost and to allocate them to those consumers who value them the most. It is important to note, however, that value depends not only on consumer preferences but also on ability to pay. Those with greater income or wealth can express greater value for goods and services and markets will tend to cater to their needs. Market outcomes, even when efficient, are not necessarily equitable. Market outcomes can result in unequal distribution of income, with the poor not getting much say in what is produced and no guarantee that even their basic consumption needs will be met.

Although market forces have often led to the loss of biodiversity, it is possible to design markets to provide incentives to conserve or enhance biodiversity. Just as with other goods and services, markets can provide incentives to provide valuable ecosystem services. In cases where biodiversity is an input into the provision of ecosystem services, having consumers pay for services provides an incentive to landowners (or others whose decisions affect biodiversity) to conserve biodiversity in order to maintain the continued supply of ecosystem services. This logic has fueled interest in “payments for ecosystem services (PES)” and related market-based approaches to conservation (Engel *et al.*, 2008).

For most goods and services traded in markets, buyers pay sellers the full cost of production and enjoy all of the benefits that the good or service provides. This result occurs when goods and services are rival: the consumption of a good or service by one individual means there is less available for others. It also occurs when the good or service is excludable: the producer can control access to the good or service so that only those who pay can consume. Under these conditions, markets can provide and allocate goods efficiently.

Public Goods and Externalities

Unlike most market goods, the existence of biodiversity and the ecosystem services that biodiversity generates are public goods whose consumption is in many respects nonrival and nonexcludable. The pleasures of observing wildlife, the benefits of climate regulation through carbon sequestration or provision of clean water through nutrient retention are all pure public goods. If these benefits are available to anyone, then they are typically available free of charge to everyone. Markets fail to provide adequate amounts of public goods. Because public goods are nonexcludable, consumers can free ride; they can enjoy the good or service for free as long as it is available. Producers have no incentive to undertake the cost of providing a good or service knowing that they cannot collect revenues to cover costs.

Even when goods and services are not pure public goods, markets may fail to supply efficient levels of provision. Consider the case of fisheries or forests where numerous harvesters can extract resources. Such common-pool resources can suffer from overharvesting because individual harvesters ignore the costs that resource depletion imposes on other harvesters (the “tragedy of the commons”). This case can be thought of as a consequence of externalities, where costs or benefits are not internalized by an individual decision maker.

What Values Are Internalized through Markets?

The degree to which markets will realize the benefits of ecosystem services generated by biodiversity depends on the degree to which those benefits can be internalized. To the extent that biodiversity contributes to rival and excludable private goods already traded in markets, its indirect value will be internalized. For example, the value of soil microorganisms that contribute to soil fertility and enhance agricultural yields is realized by farm owners through increased revenues. Farm owners have an incentive to maintain soil fertility because it enhances their bottom line. However, farm owners do not have an incentive to maintain other forms of biodiversity that enhance ecosystem services that contribute to public goods, such as nutrient retention that improves water quality downstream. The fact that we observe low levels of biodiversity in agro-ecosystems suggests that many of the benefits from maintaining biodiversity are public goods or, alternatively, that land managers are ill-informed about the potential benefits of biodiversity.

Markets can internalize some benefits even when ecosystem services are not fully rival and excludable, as the proliferation of privately owned ecotourism destinations attests. Large benefits create an incentive to make goods excludable so that providers can charge for access. Game ranches can do this on private land by fencing and guarding property boundaries and limiting access to only those who pay for it. Markets for pharmaceuticals and agricultural biotechnology also can capture benefits through patents and contracts. However, because knowledge has aspects of a public good in that it is nonrival, and to the extent that others can invent around patents or pirate patented goods, nonexcludable, the market will tend to under-supply these knowledge-driven benefits.

When markets fail to capture the value of biodiversity, the perceived opportunity cost of biodiversity loss will be too low, and the decline of biodiversity too high. Correcting this imbalance requires intervention by governments to “get the prices right,” either by using taxes and subsidies or by establishing regulations and property rights that help to create more efficient markets.

Internalizing Benefits through Policy or Other Means

Ironically, one answer to market failure resulting from public goods or externalities is the creation of new markets with the help of public policy. Market failures can be the result of the failure of markets to exist. For instance, the creation of a market for carbon would force producers and consumers to internalize the costs of carbon emission and the benefits of carbon storage. A governmentally imposed market for carbon, in addition to affecting decisions about energy production and use, would affect land markets by making lands with greater carbon sequestration and storage potential more valuable, and thus internalize the indirect value that biodiversity plays in carbon storage. Similarly, PES program focused on water quality or habitat provision would enhance the value of biodiversity conservation to the extent that doing so enhances the provision of these services. Programs such as the Conservation Reserve Program in the USA and PES (Pago de Servicios Ambientales) in Costa Rica compensate landowners for management regimes meant to enhance provision of ecosystem services and help to internalize some of the societal benefits of biodiversity conservation that landowners otherwise do not capture.

Although markets may offer economic efficiency, it may not be practical or feasible to create markets to provide incentives to maintain biodiversity. Markets require functioning institutions that can enforce property rights and, in the case of ecosystem services like water purification or climate regulation, the ability to effectively monitor the contribution of producers to the provision of ecosystem services. The ability to monitor and enforce may be lacking in countries with weak governance or simply too costly relative to the benefits of establishing a market.

Other means to try to internalize benefits include community-based programs of self-regulation and certification programs. Some communities have managed to sustainably manage resources such as fisheries, communal grazing lands, and forests through self-regulation, social customs, and norms (Ostrom, 1990). These work best in close-knit, small, and stable communities where people can oversee the actions of their neighbors. Finally, certification efforts aim to provide consumers with information about how the products they buy are produced in a sustainable manner. If consumers are sufficiently environmentally aware and back up this awareness with their pocketbooks, then certification can provide incentives for biodiversity conservation through the sustainable production of goods and services. However, there is no guarantee that consumers will not free ride and simply choose goods and services that are the least expensive.

Finally, society may opt for direct government regulation (“command and control”) to preserve biodiversity for the sake of human well-being. Government regulations can outlaw destructive practices or actions detrimental to biodiversity.

Bans on trading listed species across international borders under the Convention on Trade in Endangered Species is one example. However, failure to provide adequate resources for enforcement will drive activity into the black market rather than eliminate it. Moreover, the costs associated with such regulations may exceed their benefits, in which case human well-being will decline overall even if biodiversity is enhanced.

Glossary

Comanagement Resource users and resource managers share power and responsibilities to cooperatively manage a renewable natural resource, such as a fishery or forest. It may be two-way comanagement between a community and a government agency or three-way comanagement among a community, a bridging organization such as a nongovernmental organization or a university, and a government agency.

Elite capture Benefits from a conservation or a development initiative may be “captured” by local elites who have the economic or political power to determine who will benefit from an initiative. When this happens, an initiative can cause an increase in economic inequality.

Integrated Conservation and Development A project that links biodiversity conservation, usually of a protected area, with local socioeconomic development activities in which alternative incomes or livelihoods are introduced to reduce pressure on local natural resources.

Natural resource management This is the management of the resources that nature provides such as forests, fisheries and grasslands.

Poverty The pronounced deprivation in well-being in which a person lacks opportunities, empowerment, and security. The most common proxy for measuring poverty is per capital income. If a person lives on less than US\$1.25 a day at purchasing power parity, it is classified as “extreme poverty.” If a person lives on US\$2.00 a day or less at purchasing power parity, it is classified as “moderate poverty.”

History of Conservation and Poverty Links

Historically, the preservation of natural areas and prevention of anthropogenic impacts has been the primary goal of conservation and conservationists. Others, however, viewed the use of natural areas as economically important for improving human well-being. The conflict between preservation and use is exemplified in USA by John Muir and Gifford Pinchot – two early twentieth century contemporaries who shared the common goal of protecting wilderness in the US food division but had contrasting philosophies on how to do so. Pinchot, for example, believed sheep should be allowed to graze on public lands because it benefited shepherds and kept native grasses in check. Muir disagreed with this. He considered sheep a “hoofed locust” because of the damage they inflicted in the high sierras of California.

Muir as the founder of the Sierra Club and Pinchot as the first leader of the US Forest Service personified the historical dichotomy in conservation of preservation versus use. A century later, this dichotomy still defines how some view conservation, but it is waning in the face of growing evidence that preservation and use are points on a spectrum and there are many shades in between. In developing countries, for example, conservation initiatives may seek to conserve local biodiversity while also providing sustainable goods and services to local people.

One of the drivers of this more nuanced view is that the world's human population is expected to increase by 50% between 2000 and 2100, and meeting the basic needs of 10 billion people will require greater use of natural resources and better stewardship of our natural patrimony. Strict preservation will continue to be important in places, but the sustainable use of natural resources is likely to be central to conservation in the twenty-first century. Perhaps nowhere is this more evident than where poverty and the use of natural resource are entwined.

The poor live disproportionately in the tropics and in rural areas, where much of the world's biological diversity is also found (Redford *et al.*, 2008). The rural poor also frequently have a proportionally greater dependence on local natural resources than the better-off (Balmford *et al.*, 2008). For instance, the extremely poor are often the ones who rely most on nontimber forest products (Neumann and Hirsch, 2000), and the income and well-being of many poor households in forested areas depends greatly on the availability of forest products (Vedeld *et al.*, 2004).

Natural resources clearly matter for many rural poor, but does rural poverty matter to conservation of these resources? The debate on this point has been contentious (Sanderson and Redford, 2003, 2004; Roe and Elliott, 2004; Redford *et al.*, 2008; Roe, 2008).

To better understand the diversity of views and the evolution of thinking about conservation and poverty, it is helpful to examine a conceptual typology of the relations between conservation and poverty reduction. Based on a review of the conservation–poverty literature, Adams *et al.* (2004) identified four different conceptual views.

The first is a predominantly preservationist one. Proponents believe that poverty reduction is best left to governments and organizations with poverty reduction mandates because of its inherent complexity and because the number of poor people in the remote natural areas favored by conservationists is less than 1% of the global poor (Redford *et al.*, 2008). Dividing conservation and poverty reduction, however, may create a split that does not inherently exist in many rural communities. There is evidence that curtailing access to natural resources for local people can lead to extreme poverty such as when people are displaced by the establishment of a new protected area (Brockington *et al.*, 2006).

The second conceptual view began with a seminal United Nations (UN) report. In 1987, a UN commission produced a

report entitled *Our Common Future* (Brundtland, 1987) that called for “sustainable development.” The report argued, *inter alia*, that poverty is a major cause of environmental problems. Building on the thinking of this report, in the early 1990s, many conservationists expected that reducing poverty would help reduce destructive resource use (e.g., Wells and Brandon, 1992). In specific cases where the poor are the drivers of resource degradation, such as fuelwood consumption in parts of India and Tanzania (Baland *et al.*, 2006; Ndangalasi *et al.*, 2007), reducing poverty may in fact reduce pressure on some natural resources. Yet China, Indonesia, and Brazil have greatly reduced rural poverty while continuing to draw down their natural resources. There are two primary reasons why the alleviation of rural poverty is unlikely to break unsustainable resource-use patterns: consumption of many natural resources tends to increase with income (e.g., Narain *et al.*, 2008; Brashares *et al.*, 2011); and better-off people are often the ones who benefit the most from natural resources use because they have the capital to exploit the resources (Cavendish, 2000; Narain *et al.*, 2008).

The third conceptual view seeks to balance preservation and use. From the mid-1980s to the early 2000s, international organizations supported a number of Integrated Conservation and Development Projects (ICDPs) that aimed to both conserve biodiversity and develop the local economy by providing alternative livelihoods and incomes while curtailing local resource use mainly in protected areas. The results, however, were lackluster and much has been written about the problematic nature of ICDPs (Sanjayan *et al.*, 1997; Wells *et al.*, 1999; Adams and Hulme, 2001; McShane and Newby, 2004; Hutton *et al.*, 2005). Although interest in classical ICDPs has waned, the *de facto* integration of conservation and development activities in approaches such as Population, Health, and Environment (PHE) projects continues.

The fourth conceptual view is on the usable portion of the spectrum and focuses on the essential goods and services that natural ecosystems provide to people. Within this conceptual view, ecosystem services (Daily, 1997) and the comanagement of natural resources (Carlsson and Berkes, 2005) are found. Proponents of ecosystem service note that it is the poor who often suffer most when ecosystem services, such as clean water and clean air, decline (Wunder, 2008). Proponents may be willing to trade a reduction in the biodiversity for an ecosystem for sustainable benefits to people and protecting the remaining nature (Kareiva and Marvier, 2010). The emphasis within the study of ecosystem services is often on valuations of ecosystem services to show the importance of an ecosystem to people in general and the poor in particular (e.g., the Natural Capital Project). The implicit assumption is that a better understanding of the value of ecosystem services will improve the political will to protect these services. Yet among the extremely poor, time horizons are often short and economic discount rates are high. Hence, managing ecosystem services for long-term sustainability in places with extreme poverty may be challenging. Within comanagement of natural resources, there is the recognition that local communities have the greatest stake in the sustainable use of the local natural resources, but that community-based natural resource management can just as easily be backwards and fragmented as progressive and cohesive (Blaikie, 2006). By balancing community power with government power in a comanagement arrangement, natural resources

can in principle be more equitably and sustainably managed. Comanagement conceptual analysis and a management framework have been developed (Borrini-Feyerabend *et al.*, 2004), but long-term experience with this approach is limited.

Key Players

Understanding the key players in the conservation–poverty field is important for understanding the drivers of conservation–poverty activities. Many players have an institutional bias that emphasizes either conservation or poverty reduction.

The primary implementers of conservation–poverty projects are the international conservation nongovernmental organizations (NGOs) ranked here by 2009 overall budgets: The Nature Conservancy (TNC), the WWF, Conservation International (CI), the International Union for the Conservation of Nature (IUCN), Wildlife Conservation Society, Fauna and Flora International, African Wildlife Fund, the BirdLife International network, and Wetlands International.

Among development NGOs in 2011, those with an active interest in poverty–conservation issues include CARE International members, Pathfinder International, and World Education. CARE in East Africa has a long-time presence in the poverty–conservation field.

Among development agencies working on poverty and conservation issues, the standouts are Department for International Development (DFID), United States Agency for International Development (USAID), United Nations Development Program (UNDP), and the World Bank. DFID was the first government aid agency to extensively research the links between conservation and poverty reduction. USAID fostered community-based natural resource management in the 1990s and PHE projects more recently. UNDP is an important convener of conservation–poverty meetings. The World Bank was a large implementer of ICDPs in the late 1990s and has published influential studies examining the links between environment and poverty. The World Bank is also a key player in reduced emissions from deforestation and degradation that aims to link forest preservation, reduced CO₂ emissions, and poverty reduction. Norway and its bilateral aid agency Norwegian Agency for Development Cooperation have joined with the World Bank in this work. Other bilateral agencies with a history in poverty and conservation projects include Danish International Development Agency (Denmark), Swiss Agency for Development and Cooperation (Switzerland), Swedish International Development Cooperation Agency (Sweden), Canadian International Development Agency (Canada), Finnish International Development Agency (Finland), Kreditanstalt für Wiederaufbau (Germany), Deutsche Gesellschaft für Internationale Zusammenarbeit (Germany), and Fonds Français pour l'Environnement Mondial (France).

Between the conservation and development organizations is the London-based International Institute for Environment and Development. This organization has been at the center of conservation–poverty issues since the early 2000s, as a convener, publisher, and an analytic force.

Other international organizations important to conservation and poverty reduction include Consultative Group on

International Agriculture Research members, the Center for International Forestry Research, World Agroforestry Center, and the World Fish Center. The Global Environment Facility and the Convention on Biological Diversity Secretariat are also influential multilateral players in conservation and poverty issues.

Does Conservation Benefit the Poor?

Evidence Showing Conservation has Benefited the Poor

Perhaps the central question in conservation and poverty studies is to what extent does the conservation of biodiversity actually benefit the poor and the extreme poor? Much of the existing conservation–poverty knowledge is based on anecdotal evidence for a variety of reasons (Ferraro and Pattanayak, 2006). There is, however, suggestive empirical evidence that conservation initiatives can measurably benefit the poor and the extremely poor (see Leisher *et al.*, 2010 for the full review). The best evidence of conservation initiatives that have reduced poverty comes from forestry, fisheries, grasslands, and nature-based tourism and is summarized here.

Forestry

Within the forestry sector, evidence of conservation benefiting the poor is largely found in community-based timber enterprises. Timber is harvested in such enterprises at levels that ensure the ecological integrity of the forest, whereas the income generated from the timber sales contributes to local poverty reduction. Such enterprises are frequently based on contractual arrangements between communities and companies to supply fiber, pulp, or construction timber.

A study of 14 community-forestry timber enterprises in developing countries found that they can be profitable (Molner *et al.*, 2007), and in Mexico, community-forestry enterprises have helped reduce local poverty (Antinori and Bray, 2005). For nature, community forestry can also be a benefit. There is evidence from Nepal (Gautam *et al.*, 2002), Mexico (Bray *et al.*, 2003), and Vietnam (Nguyen *et al.*, 2009) that community forestry has led to increases in forest cover.

It is not only timber that can benefit poor communities but also the forest itself. A meta-analysis of 51 case studies from 17 countries found that forest environmental income represents on average 22% of the total rural household income (Vedeld *et al.*, 2004). Fuelwood and nontimber forest products are often an integral part of the livelihood strategies of the poor and extremely poor and maintaining an intact forest has benefits to the rural poor that are often overlooked (Naughton-Treves *et al.*, 2011).

Fisheries

Near-shore fisheries provide a high percentage of animal protein for people in poor countries, but many near-shore fisheries are fished beyond the limits of sustainable yields (FAO, 2010). One strategy to address this is the creation of no-take zones. Such zones provide space for fish to grow bigger, and bigger fish usually have exponentially more offspring than smaller fish (PISCO, 2007). After several years of protection, fish may spillover into the area outside the no-take zone where they can be caught (Gell and Roberts, 2003). Greater fish catches generate

more income for fishers and hence help reduce poverty, whereas the no-take zone provides protected habitat for marine life.

In places where many people are poor, and fishing is in crisis, there may be medium-term poverty reduction benefits from no-take zones. WRI (2005) and Leisher *et al.* (2007) found that spillover from two community-managed marine areas in Fiji roughly doubled local incomes within 5 years of establishing the no-take zone compared with control sites, and women were the primary beneficiaries.

The indirect benefits to the poor may also be important. Organizing a community to manage a no-take zone often strengthens the social fabric of the community, giving them a ready decision-making body and a more unified voice to address other community issues (Leisher *et al.*, 2007). The stronger social cohesion also improves local security and empowers local decision making, two key elements of poverty reduction (World Bank, 2001).

There is evidence that no-take zone management is more effective where there is active participation of local communities in the resource management (McClanahan *et al.*, 2006). There is also evidence that size matters. If a no-take zone is too large, spillover will not offset the losses to fishers from closing sections of the fishing grounds (PISCO, 2007). From the perspective of fisheries, networks consisting of a number of smaller marine protected areas may be preferable to a few very large marine protected areas (IUCN-WCPA, 2008).

Grasslands

Grasslands can have greater grass productivity with grazing than without grazing (Guo, 2007), and some types of grassland are ecologically dependent on grazing to maintain their biodiversity (Fratkin and Mearns, 2003). Within grasslands, livestock is often the primary form of wealth for local communities (Eriksen and Watson, 2009), and these communities can be among the extreme poor when measured by a multidimensional definition of poverty (e.g., Glew *et al.*, 2010). The relationship among grazing, biodiversity, and local livelihoods is what underpins grasslands conservation projects that have benefited the poor. Pastoralism, especially in drylands, may be one of the few land uses that is genuinely compatible with “formal” nature conservation (WISP, 2008).

Studies in a South African community-managed grassland (Leisher *et al.*, 2011a), in the Mongolian Gobi grasslands (Leisher *et al.*, 2011b), and in northern Kenya's grasslands (Glew *et al.*, 2010) used household surveys and remote sensing to measure differences before and after and between impacted and matched control areas using a variety of socioeconomic and ecological indicators. These studies identified a number of benefits to the poor and extreme poor as well as greater net primary productivity of project grasslands compared with before the project and matched control sites. The evidence from these studies suggests that better grasslands management can benefit both the poor and the grasslands themselves.

Nature-Based Tourism

Nature-based tourism can include community-based operations on one end and all-inclusive international ecolodges and safari operations on the other. Tourism can offer opportunities for reducing poverty via jobs in the formal tourism sector, such as accommodation and guiding, and in new

markets for local services and products, such as sales of crafts, cultural services, food, and drinks. Tourism may also be associated with infrastructure development, such as roads, telecommunications, and health care facilities, which when provided for the benefit of tourists, benefit the poor as well.

A meta-review of 27 tourism case studies in Asia found income gains for all economic levels but with those already better-off gaining most (Shah and Gupta, 2000). In Zambia, a World Bank Study (2007) found that nature-based tourism had reduced poverty, but those with most assets benefit up to 50% more than the extremely poor. The indirect benefits may be important to the poor as well. There is a multiplier effect from tourism that creates opportunities and downstream effects for casual laborers, crafters, and small businesses (Ashley and Roe, 2002). The indirect benefits, such as better infrastructure, can also benefit poor people (e.g., Shackleton *et al.*, 2007). Where tourism operators commit to hire and train local people, the financial benefits to a local community can be substantial (Davis, 2005).

Although there is suggestive empirical evidence that a conservation initiative can benefit the poor from community-forestry timber enterprises, no-take zones for fish, grasslands management, and nature-based tourism, there are other areas where the evidence of poverty reduction is even more limited but may have potential for benefiting the poor, including nontimber forest products, payments for environmental services, mangrove restoration, protected area jobs, and agroforestry (Leisher *et al.*, 2010). Some, such as nontimber forest products and payments for environmental services, have been well studied but the evidence is inconclusive. Others remain to be studied rigorously.

Evidence Showing Conservation has Hurt the Poor

The evidence that conservation initiatives have hurt the poor comes primarily from the establishment of new protected areas that displaced local people (Brockington *et al.*, 2006). This can be either physical displacement, such as eviction from their homes, or economic displacement by excluding people from an area that is important to their livelihoods (Cernea, 2005). Regardless of the type of displacement, the impacted people are often worse-off economically, culturally, and socially. For indigenous people displaced by a conservation initiative, the negative impacts can continue for decades after the displacement (Colchester, 2003).

The number of people and the number of places where local people have been displaced by a new protected area are disputed (Borgerhoff-Mulder and Coppolillo, 2005; Wilkie *et al.*, 2006), but most of the cases occurred before 1980. In recent decades, the impacts of displacing people from a new protected area have become better understood, and most donors and conservation organizations are reluctant to participate in such projects.

Other Key Issues

In addition to the issue of whether conservation initiatives have helped or hurt the poor, there are several other key issues within conservation and poverty.

Perhaps foremost is the considerable heterogeneity among poverty indicators used to measure poverty impact. The choice of indicators is often driven by differing definitions of who is poor (Agrawal and Redford, 2006). Existing definitions of "poor" may be qualitative or quantitative, temporal or points-in-time, and may be multidimensional or one dimensional (Ravallion, 2008). The poverty reduction impact of a conservation initiative depends greatly on how poverty is defined and the indicators used to measure it.

Conservation and poverty reduction links are often dynamic and locally specific (Kepe *et al.*, 2004; Sanderson and Redford, 2004; BirdLife, 2007). Thus, universal models applicable to multiple local contexts for jointly addressing conservation and poverty are unlikely. Instead, habitat types where the biological diversity itself is fundamental to the benefits to people may hold more promise for conservation and poverty reduction. Examples of this are fisheries in which greater biodiversity produces greater biomass (Worm *et al.*, 2006) and grasslands that have coevolved with grazers and now depend on grazing to maintain plant diversity (Fratkin and Mearns, 2003).

Elite capture of benefits is also an issue. The wealthier segments of a population participating in a conservation or development initiative may "capture" the majority of the benefits (e.g., Jagger, 2008; Bandyopadhyay and Tembo, 2009). Part of the reason is because the better-off generally have greater human and financial capital, which allows them to benefit more from an initiative (Weber *et al.*, 2011), and they are also more likely to participate in an initiative (Groom *et al.*, 2010). Where local leaders are not downwardly accountable to their constituents, the local elites may shape a conservation initiative to benefit themselves (Jumbe and Angelsen, 2006).

A key issue often overlooked is that generating benefits from conservation to the poor and especially the poorest of the poor is frequently more about increasing biomass than increasing biodiversity (Balmford *et al.*, 2008). For example, the volume of fish is usually more important to a small-scale fisher than the variety. Although in a few natural ecosystems, biomass productivity may be linked to species biodiversity, in other cases, a managed and less diverse ecosystem may provide greater production of the biomass that poor people value than a natural ecosystem. Examples of this include woodlots for firewood production and grasslands converted to agriculture.

A final issue is the limited political will to improve the well-being of people in hard-to-reach areas. Rural, impoverished populations tend to be politically marginalized and expensive to reach with services. Conservation initiatives are frequent in remote areas, and the national government's willingness to work in these areas on conservation-poverty issues may be lacking. This has implications for the sustainability of externally driven initiatives, especially those with exit strategies dependent on the government assuming a greater role in service delivery.

Trends Within Conservation and Poverty

Within conservation and poverty reduction, what is happening at the global level influences what happens at the local level. Herein, we look at the macro- and microlevel trends within conservation and poverty.

Although the proportion of people under US\$1.25 a day is dropping, the absolute number of the extreme poor continues to climb in most countries (Table 1). Much of the growth in the number of poor is in urban areas, but it is in rural areas where poverty is most often a chronic condition. It is also in rural areas where the extreme poor tend to be most dependent on the goods and services nature provides. Given existing demographic trends, the number of poor people is likely to increase in many of the remote, rural places where conservation organizations work.

Poverty reduction is also becoming more challenging. The Millennium Development Goals signed by 192 of the world's governments call for reducing poverty by 50% between 1990 and 2015 as the top priority. Even if this goal is achieved, this would leave more than 2 billion people still in poverty. Moreover, the easier gains would be past because those just below the poverty line will have moved over the line, and the ones left will require greater effort. Inside and outside of conservation, poverty will remain one of the greatest challenges globally.

Table 1 Number of people living on less than US\$ 1.25 a day (millions)

Region	1990	2005	Change
South Asia	579	595	+ 16
Sub-Saharan Africa	295	387	+ 92
China	683	208	- 475
East Asia and Pacific (minus China)	190	109	- 81
Other	68	72	+ 4

The World Database on Protected Areas shows that the rate of establishing new protected areas has dropped sharply, declining from a historic high of 2920 in 2002 to 40 in 2006 (UNEP-WCMC, 2009). For a variety of reasons, the focus within conservation has shifted away from establishing new protected areas. Protected areas will remain the core conservation strategy of most governments, but much of the conservation efforts in the twenty-first century are likely to be outside protected areas. This is especially true for conservation-poverty issues where efforts outside of designated protected areas are likely to yield greater conservation gains with greater poverty reduction benefits than inside protected areas.

Another macro trend is the devolution of power. The locus for decision making in many countries has shifted to the subnational level. The principle is that power should be devolved to the lowest feasible level. The assumption is that the closer decision making is to the problem, the more likely the problem will be addressed successfully. For conservation, this may entail working more with local-level governments. For conservation and poverty reduction, this may result in focusing more on restoring degraded habitats than preserving intact habitats given the presumed development focus on most local-level governments.

At the microlevel, conservation organizations have responded by making people more central to their mission. TNC and CI both changed their mission statements to highlight the benefits to people from conservation. Three of the largest US foundations that fund conservation organizations (Moore, Packard, and MacArthur) have shifted their funding toward more people-centered conservation.

Figure 1 Number of conservation-poverty publications by year.

There is also a growing recognition within international conservation organizations that the social sciences are as important as the natural sciences. After several decades of defining where the Earth's maximal biodiversity is located and where it is most threatened, conservation organizations know where they need to work. What is lacking is a greater understanding of how they need to work. One promising development comes from the Nobel Prize-winning economist Elinor Ostrom. She identified how communities that self-organize to manage common-pool resources, such as fisheries and forests, can avoid the tragedy of the commons. Ostrom found 10 factors that are predictive of communities self-organizing to manage socioecological systems (Ostrom, 2009). Gutierrez *et al.* (2011) did similar work for marine areas and highlighted the success factors for fisheries comanagement. Yet these success factors were determined via ex-post quantitative analysis. Identifying and measuring the level of key factors before a conservation initiative begins (*ex-ante*) could improve conservation success. Turning the known conditions for success into site-screening tools that can be used by social scientists is a nascent trend in conservation.

Another micro trend is the greater focus on measuring the impact of a conservation initiative on local people and the poor. Ferraro and Pattanayak (2006) provided a good summary of why this is needed and approaches that can separate what happened because of a conservation initiative and what would have happened without the conservation initiative. The authors call for greater use of baselines, measure of covariates, and matched control groups. Several international conservation organizations have been working together on improving conservation impact measures (www.conservationmeasures.org).

A final trend is the growing interest in conservation-poverty issues as evidenced by the growth in the literature on the topic (Figure 1). A comprehensive literature review in June 2010 found 430 articles, books, and publications on conservation-poverty topics (Leisher *et al.*, 2010). Few were published before 1998, but the field began to grow rapidly around 2000. In recent years, the average is about 50 new publications a year on the topic.

Conclusions

As a former rancher in North Dakota, President Teddy Roosevelt believed in using the land to benefit people but wanted to balance this with protection of special places. He wanted both preservation and use of natural areas, and that is why he gave his political support to both Muir and Pinchot. Roosevelt recognized that preservation and use need not be an either/or choice but a spectrum with strict preservation on one end and destructive use on the other. Usage that is sustainable can enable biodiversity preservation. It also addresses the reality of several billion people globally needing resources to move out of poverty.

The knowledge base of conservation-poverty issues continues to grow and the rigor of new studies has increased such that there is far more evidence of impacts than a decade ago. On balance, however, the evidence base is still limited and

largely suggestive of how the poorest of the poor may benefit from conservation.

Glossary

Alien species A species introduced by humans (deliberately or accidentally) outside its native distributional range.

Bioregional management An approach to management which encompasses whole ecosystems so as to protect and restore their components sustainably.

Biosphere reserves Sites established by countries and recognized under UNESCO's Man and the Biosphere (MAB) Programme to promote sustainable development by combining core protected areas with zones where sustainable development is fostered.

Conservancy A collection of mostly agricultural properties which are cooperatively managed under a single management plan, bound with a voluntary agreement between the landowners and the state.

Conservation planning The systematic and spatially explicit identification of areas important to achieving particular biodiversity conservation targets.

Conservation targets Quantitative estimates of the amount of each species or ecosystems that should be included in a conservation plan.

Driver of change A natural or human-induced factor that directly or indirectly causes a change in an ecosystem.

Easement An agreement which transfers certain specified rights (e.g., development, timber harvesting, mining, etc.) from the landowner to a third party. These transfers can be attached to the property title deed and are either acquired by donation or purchase.

Ecologically sustainable management Management which focuses on the wise use, conservation and enhancement of natural resources so that ecological processes, on which life depends, are maintained, and the total quality of life, now and in the future, can be improved.

Ecosystem services Benefits that people receive from ecosystems including provisioning, regulating, supporting and cultural benefits.

Gap analysis A tool used in conservation to identify gaps (e.g., ecosystems or species not represented in the current network of protected areas).

Multifunctional landscapes Landscapes which provide multiple environmental, social and economic functions and are able to achieve multiple societal needs including energy and food production, management of waste, conservation of biodiversity, and management of water quantity and quality across the landscape; the improvement of landscape heterogeneity and therefore resilience; and the provision of recreational opportunities.

Off-reserve conservation Conservation efforts which focus on the management of whole landscapes, complementing formal protected areas with other (potentially cheaper) property rights mechanisms including the creation of management agreements and the designation of conservation easements.

Payment for ecosystem services Contractual or negotiated agreements where ecosystem service beneficiaries compensate ecosystem stewards for enhancing, maintaining, reallocating or offsetting damage to ecosystem services.

Property rights instruments Mechanisms which support conservation on private land and vary from voluntary to contracted agreements between the conservation agency and the landowner(s). They can include management agreements and conservation easements.

Protected area A clearly defined geographical space, recognized, dedicated and managed, through legal or other effective means, to achieve the long-term conservation of nature with associated ecosystem services and cultural values.

Protected Areas: History, Purpose and Gaps

Protected areas have long been the mainstay of humanity's attempts to conserve areas deemed to be of natural, cultural, or ecological importance. As long as 2000 years ago ancient societies in Greece, Rome, Asia, and Africa are known to have set aside areas as sacred groves or sites (Chandrashekara and Sankar, 1998), while European societies protected hunting grounds for the use of royalty and the wealthy as long as 1000 years ago. Some of these areas are still in existence today. But it was only in the nineteenth century that the modern protected areas movement took hold globally with the establishment of large protected areas like Yellowstone National Park (1872) in the USA, Royal National Park in Australia (1879), and the Kruger National Park in South Africa (1898) (Box 1).

The motivations behind these protected areas historically were multiple, for example, the protection of game species in colonial Africa or scenic wilderness landscapes in North America (Chape *et al.*, 2005). Until recently, in fact, the motivations have seldom been the protection of biodiversity *per se*, and have usually been based on culturally valued aspects of biodiversity and the broader landscape, for example, charismatic megafauna, attractive habitats, important watersheds, recreational areas, or endangered species. It is therefore important to note that the current set of protected areas serve many functions besides biodiversity conservation; a fact recognized by the IUCN (1994), which lists multiple functions of protected areas including: scientific research, wilderness protection, preservation of species and genetic diversity, maintenance of environmental services, protection of specific

Box 1 What is a protected area?

The IUCN, the International Union for Conservation of Nature, defines a protected area as: "a clearly defined geographical space, recognized, dedicated and managed, through legal or other effective means, to achieve the long-term conservation of nature with associated ecosystem services and cultural values." It has created a system (the IUCN Protected Areas Categories System) that includes six distinct categories of protected areas:

- Ia. Strict Nature Reserves are strictly protected areas set aside to protect biodiversity and also possibly geological/geomorphical features, where human visitation, use, and impacts are strictly controlled and limited to ensure protection of the conservation values.
- Ib. Wilderness Areas are usually largely unmodified or slightly modified areas, retaining their natural character and influence without permanent or significant human habitation, which are protected and managed so as to preserve their natural condition.
- II. National Parks are large natural or near natural areas set aside to protect large-scale ecological processes, along with the complement of species and ecosystems characteristic of the area, which also provide a foundation for environmentally and culturally compatible, spiritual, scientific, educational, recreational, and visitor opportunities.
- III. Natural Monuments or Features are set aside to protect a specific natural monument, which can be a landform, sea mount, submarine cavern, geological feature such as a cave or even a living feature such as an ancient grove.
- IV. Habitat/Species Management Areas aim to protect particular species or habitats and their management reflects this priority.
- V. Protected Landscape/Seascape is an area where the interaction of people and nature over time has produced an area of distinct character with significant, ecological, biological, cultural, and scenic value; and where safeguarding the integrity of this interaction is vital to protecting and sustaining the area and its associated nature conservation and other values.
- VI. Protected area with sustainable use of natural resources is an area that conserves ecosystems and habitats together with associated cultural values and traditional natural resource management systems. They are generally large, with most of the area in a natural condition, where a proportion is under sustainable natural resource management and where low-level nonindustrial use of natural resources compatible with nature conservation is seen as one of the main aims of the area

In this article the term protected area refers to Categories I and II unless otherwise stated.

Figure 1 Global growth in protected areas. Reproduced from IUCN and UNEP-WCMC (2009) *The World Database on Protected Areas (WDPA): January 2009*. Cambridge, UK: UNEP-WCMC.

natural and cultural features, tourism and recreation, education, sustainable use of resources from natural ecosystems, and maintenance of cultural and traditional attributes. When viewed from this perspective, the growth in protected areas and their role in society has been substantial. From a mere 10,000 protected areas in 1962, today the World Database on Protected Areas totals 114,000 sites comprising 12.9% of the earth's land surface contributing in many varied direct and indirect ways to economies, societies, and individuals (Dixon and Sherman, 1991; Chape *et al.*, 2008; Figures 1 and 2).

However, when viewed through the lens of biodiversity conservation, the bottom up and rather *ad hoc* approach to protected area establishment, further exacerbated by the fact that protected areas were often only established in remote and unproductive areas that no-one else wanted (Pressey *et al.*, 1996; Norton, 2000; Scott *et al.*, 2001), has resulted in an inefficient and ineffective global network of protected areas (Brooks *et al.*, 2004; Rodrigues *et al.*, 2004; Hoekstra *et al.*, 2005).

The first bias in this global coverage is seen when distinguishing between terrestrial, inland water, and marine

systems. While 10–12% of the land surface area and inland water areas fall within protected areas, marine systems have less than 1% of their area protected (Chape *et al.*, 2008). Within terrestrial systems the biases are even more apparent with poorly protected biomes like temperate grasslands, Mediterranean forests, and tropical coniferous forests (around 2% of their area is conserved) contrasting with (the less economically productive) flooded grasslands, tundra, temperate coniferous forests, mangroves, and boreal forests, which have the highest percentage area under protection (7–14%; Figure 3; Mace *et al.*, 2005). Global data at the ecosystem level for freshwater and marine systems are currently unavailable, but at a regional scale Chape *et al.* (2008) showed that only Australasia and North Eurasia have more than 2% in marine protected areas, while data seem to indicate that Australasia, the Caribbean, East Asia, and Eastern and Southern Africa have around 15% of their inland water systems protected. Protected area coverage of inland waters is low in North America and North Eurasia – areas with large areas of inland waters. In a national study of freshwater protected areas Nel *et al.* (2007) found that more than 90% of all main rivers in South Africa fall completely outside statutory protected areas, while half of the remaining rivers form boundaries of protected areas and therefore less than 5% of main rivers in the country are core rivers within protected areas, receiving protection on both sides of their river bank.

At the species level, using data on terrestrial vertebrates, Rodrigues *et al.* (2004) found that 12% of mammals, birds, turtle, and amphibians do not fall into the global network of protected areas. This number doubled if small protected areas were excluded. The number was highest for amphibians, for threatened species, and for areas with many endemic species. The authors point out that their numbers are certainly an underestimate of terrestrial species falling between the cracks of protected areas. In the freshwater and marine realms major

gaps in species distribution data (e.g., Lévêque and Balian, 2005) imply that little is known about the contribution of protected areas to biodiversity conservation. But considering the low percentage of area protected in the case of the world's oceans, marine species are probably worse off than their terrestrial counterparts. This is further supported by growing evidence that freshwater systems are more threatened than terrestrial ones (Dudgeon *et al.*, 2006) and the fact that many rivers actually form the boundaries of protected areas and cannot necessarily be considered conserved by the protected area (Nel *et al.*, 2011). The gaps in freshwater species conservation are potentially large.

Results from these gap assessments in global protected areas, as well as improvements in the data availability and the science of conservation planning, have all added to calls for a more systematic approach to the establishment of protected areas (Box 2).

Beyond Protected Areas

Despite the proliferation of new data, methods and results from conservation planning helping to plug some of the gaps in the global protected area network, it is unlikely that protected areas alone will stem the tide of biodiversity loss. In fact recent evidence suggests that despite increases in the extent of protected areas, biodiversity losses continue (Butchart *et al.*, 2010). While some of this has to do with the limitations of protected areas, for example, limited size, area and resources for expansion, and a lack of spatial congruence with biodiversity conservation needs (Lindenmayer and Burgman, 2005), at the center of this conundrum lies conservation's inability to secure societal commitment and adequate responses to address the drivers of change in biodiversity both inside and outside of protected areas.

Box 2 The rise of systematic conservation planning

In their review of systematic conservation planning, [Margules and Pressey \(2000\)](#) argue that protected areas should ideally fulfill two roles with respect to biodiversity conservation: (1) they should *represent* or sample the full variety of biodiversity at all levels of organization (genes, species, and ecosystems); and (2) they should ensure the persistence or long-term survival of this biodiversity that they represent through maintaining the ecological and evolutionary processes necessary to this persistence.

As [Margules and Pressey \(2000\)](#) reflect, it is clear that a “structured systematic approach to conservation planning provides the foundation needed to meet (the) objectives” of representation and persistence of biodiversity within the constraints of limited resources and competition for land. They propose a six-step framework for systematic conservation planning, which is based on spatial biodiversity data, as well as quantitative targets – for example, 10% of each habitat, 200 individuals of a species – which explicitly set out the goals of the conservation plan.

Conservation planning deals with the identification of geographic priority areas that contain species, habitats or processes essential to achieving the conservation goals of a region or country ([Margules and Pressey, 2000](#)). It uses techniques concerned with the maximal coverage problem including complementarity-based reserve selection and linear programming algorithms. Systematic conservation planning is said to be effective at achieving the twin objectives of representation and persistence due to its cost efficiency, its defensibility and flexibility in the face of competing land and resource requirements, and its accountability in allowing the outputs of plans to be critically reviewed ([Margules and Pressey, 2000](#)). These past two decades have witnessed a proliferation of tools, techniques, software, databases, and research outputs devoted to the task of systematically identifying spatial priority areas for conservation action – see [Moilanen et al. \(2009\)](#) for a review.

These drivers, for example, habitat loss, overexploitation, alien species introductions, and climate change have resulted in significant losses to biodiversity, especially over the past 50 years ([MA, 2005](#)) and are set to increase into the future ([Butchart et al., 2010](#); [CBD, 2010](#)). While their impact on biodiversity outside of protected areas is evident (e.g., [MA, 2005](#); [Butchart et al., 2010](#)), more subtle changes have been wrought by these drivers on the biodiversity inside protected areas. [Chape et al. \(2008\)](#) highlight the large range of physical (e.g., fire), biological (e.g., alien species), social (e.g., community opposition), political (e.g., political support), economic (lack of resources), and managerial (e.g., lack of planning) threats faced by biodiversity within protected areas. Climate change poses a new and largely uncertain threat to these areas with some projections highlighting major biodiversity losses (e.g., [Erasmus et al., 2002](#)). [Pressey and Logan \(1997\)](#) add to these constraints the limited effectiveness that protected areas can have on some drivers of change inside and outside of protected areas, for example, salinization and airborne chemical pollution.

If the conservation community is to be successful in addressing the drivers of change in biodiversity then two things are clear: (a) a reliance on protected areas will not be enough; and (b) conservation will have to start engaging with the areas and sectors from which the drivers of biodiversity loss originate. Both of these realizations signal a move for the conservation community beyond protected areas – a move that begun over two decades ago (e.g., [Hale and Lamb, 1997](#)). There has since been significant effort invested in the development of conservation interventions focused outside protected areas. This article reviews the current set of conservation approaches using a framework to categorize approaches and then explores each category to highlight developments, challenges, and opportunities.

Conserving Biodiversity Outside of Protected Areas

A Typology of Conservation Approaches

Biodiversity conservation is a broad and diverse initiative ranging from local site scale interventions to global political interventions. In the past few decades approaches to conservation have increased in number, scope, and complexity in

terms of what the approaches aim to conserve, as well as how, when, and where they go about conserving biodiversity ([Redford et al., 2003](#)). The focus of conservation efforts has evolved over time and today ranges from specific species, through landscapes, to people, and their well-being. As this focus has evolved so too have the approaches with which to conserve these elements. [Redford et al. \(2003\)](#) reviewed 13 conservation organizations and 21 approaches used to identify where or how conservation should be done. Their results illustrate the enormous diversity of approaches, scales, and principles underpinning the approaches.

This article, using a framework based on several existing classifications of conservation approaches, presents and explores the current diversity of approaches to conservation beyond protected areas. [Table 1](#) shows the nine approaches used by [McNeely et al. \(2005\)](#) who focused on the most widely used and discussed responses to biodiversity loss. Their list includes protected areas; wild species management; regional planning, agricultural/forestry and fishery policy; governance; multilateral environmental agreements; education/communication; local capture of benefits; and private sector activities. [Mawdsley et al. \(2009\)](#) identified four approaches in exploring conservation options for climate change. They classified biodiversity conservation responses into (a) land and water protection and management; (b) direct species management; (c) monitoring and planning; and (d) law and policy. Based on these two categorizations it appears that there are six broad approaches to conservation ([Table 1](#)). None of these approaches is mutually exclusive and in fact conservation usually relies on a combination of approaches to be successful ([Young and Gunningham, 1997](#)).

Examining the approaches with respect to their type of action, it is possible to divide them into two main types of actions: direct or enabling. Direct actions are those that involve on-site and on-the-ground management of areas and species and would include approaches 1 and 2 in [Table 1](#). Enabling actions are those that happen mostly off-site and make it possible for the direct action to take place and include approaches 3, 4, 5, and 6. While acknowledging the importance of enabling actions to conserving biodiversity outside of protected areas, this article does not explore them in detail, rather focusing on approaches to land and water protection

Table 1 Classification of conservation approaches based on McNeely *et al.* (2005) and Mawdsley *et al.* (2009)

Class	Approaches to conservation	McNeely <i>et al.</i> (2005)	Mawdsley <i>et al.</i> (2009)	Focus of approach
I	Land and water protection and management	Protected areas	Land and water protection and management	Direct action
II	Species management	Wild species management	Direct species management	Direct action
III	Monitoring and planning	Regional planning	Monitoring and planning	Enabling action
IV	Law, governance and policy	Agricultural/forestry & fishery policy Governance Multilateral environmental agreements	Law and policy	Enabling action
V	Incentives and partnership	Local capture of benefits Private sector activities		Enabling action
VI	Outreach and education	Education/Communication		Enabling action

and management and some approaches to *in situ* species management, referring only to the other approaches where relevant in supporting these first two approaches.

Land and Water Protection and Management

There are many conservation approaches currently in use in the protection and management of land and water for biodiversity conservation (**Box 1**). In differentiating these approaches it is useful to distinguish their primary management objective. For example, the range of protected areas recognized by the IUCN considers that categories I–III are mainly concerned with the conservation of natural areas where human intervention and modification of the environment are limited. Categories V and VI generally involve greater intervention and modification. Category IV sits somewhere in the middle with its primary goal the interventionist management of certain natural conditions or processes. However, there are many areas, which fall outside of these categories, that can play a valuable role in conserving biodiversity. These include small areas, areas without formal management arrangements or proper security of protection, or areas that are too transformed to be listed (Pressey and Logan, 1997). The value of these areas was recognized in early work by proponents of bio-regional management – an approach to management, which sought to encompass the whole ecosystems so as to protect and restore their components sustainably (WRI, 1996; UNESCO, 1995; Wells and Brandon, 1993). Work in this field included the UNESCO Man and the Biosphere Reserve Programs, as well as Integrated Conservation and Development Projects. Since then there has been much scientific and practical progress in the area of whole ecosystem management, which this article summarizes and explores.

From Strict Protection to Living Landscapes: A Framework for Review

While the world has historically relied on state-owned reserves and land-use regulations to conserve biodiversity; the right

Figure 4 A framework for reviewing the contribution of areas of land and water to biodiversity conservation. Starting at the bottom right hand corner the framework moves from “strictly protected areas,” reflecting the more traditional approach to protected areas managed almost exclusively for biodiversity conservation. The next category is “living lands and waters”, which are areas managed primarily for biodiversity conservation with some extractive uses limited to the ecologically sustainable management of areas of land and water to support life of all forms. “Working lands and waters” are mostly agricultural lands managed primarily for extractive uses while attempting to conserve biodiversity at the same time. The final category is “production areas” of land and water where the management focuses exclusively on maximizing extractive and productive uses and biodiversity conservation is not an objective.

combination of beyond protected area conservation mechanisms and incentives has shown tremendous potential in conserving biodiversity outside of protected areas. The framework depicted shows the evolution of conservation approaches to managing biodiversity on land and in the water (**Figure 4**). Starting at the bottom right hand corner the framework moves from the strict traditional approach to protected areas managed almost exclusively for biodiversity conservation, through the less stringent IUCN Category V and VI areas where some level of human activity and resource

extraction is permissible, through areas managed for both conservation and production purposes, to a set of final areas of land and water where the management focuses exclusively on maximizing extractive and productive uses. The evolution also signals a shift from mostly state-owned land to mostly private and communal land. As illustrated in this framework there are overlaps in this transition from strict protected areas to intensive extraction and it is likely that in all areas some contribution to biodiversity conservation, as well as resource use and benefits is possible. While the opposite extremes of this framework are relatively well understood and classified in terms of their contribution to biodiversity conservation and production uses, the transition zone is less clear and as yet no single classification exists for the different types of conservation approaches within this zone. There are many terms currently in use to describe the conservation approaches including off-reserve, biosphere, conservancy, easement, biorregion, etc. The framework proposes two main categories within this transition zone differentiated based on primary management objectives as either: biodiversity conservation with some extractive uses (living lands and waters) or extractive uses, which try to conserve biodiversity at the same time (working lands and waters). In the former category one would expect a more intact or natural landscape with low levels of extractive use, for example, grazing, wildlife farming, or fuelwood harvesting. In the other category the landscape would be converted into production lands, but with an attempt to limit losses to biodiversity, for example, biodiversity-friendly agriculture and sustainable forestry.

Living Lands and Waters

The idea behind this broad approach to conservation is the ecologically sustainable management of areas of land and water to support life of all forms (e.g., Driver *et al.*, 2003). Ecologically sustainable management focuses on the wise use, conservation and enhancement of natural resources so that ecological processes, on which life depends, are maintained, and the total quality of life, now and in the future, can be improved (Knight and Cowling, 2003). This concept has also found traction in the management of river systems. Richter *et al.* (2003) define ecological sustainable management in the context of water management as “management that protects the ecological integrity of affected ecosystems while meeting the intergenerational human needs for water and sustaining the full array of other products and services provided by natural freshwater ecosystems. Ecological integrity is protected when the compositional and structural diversity and natural functioning of affected ecosystems are maintained.” While there is as yet no commonly accepted definition of “sustainable management” or “ecological integrity” it is clear that such management approaches focus on maintaining functional ecosystems.

These areas of land and water can be under many forms of tenure, but are largely privately or communally owned and used to derive income or livelihoods for the landowner(s). Many vast tracts of land can be said to exist in this state even in the absence of direct conservation interventions, for example, the large rangelands areas in Africa, Australia and North

America or remote mountain catchment areas, forests and their rivers (e.g., Wallis de Vries *et al.*, 1998; Schwartzman *et al.*, 2000; Kessler and Thomas, 2006). However, the contribution of such areas to biodiversity conservation, while currently high, is uncertain and almost certainly declining if one considers the increases in drivers of biodiversity loss. Overgrazing, changes in fire management practices, climate change, and habitat loss all threaten to reduce the contribution made by these areas and have motivated many conservation organizations to work on ensuring the sustained contribution of the areas to conservation.

In an effort to secure the contribution of areas of land and water (especially those with private or communal tenure) to biodiversity conservation, conservation organizations have developed and used a range of conservation instruments developed for managing biodiversity outside of protected areas. Young *et al.* (1996) introduce the wide array of instruments available, which Pence *et al.* (2003) group into five categories: motivational, educational, and information instruments; voluntary instruments; property-rights instruments; financial mechanisms; and regulation.

Motivational, educational, and information instruments include a wide variety of approaches, which aim to encourage attitudinal change and the adoption of an ethic of conserving nature on private land and can also be combined with the other instruments to help support conservation on private land. Voluntary instruments allow for conservation areas to be set aside on private land and in return some technical assistance may be offered. They are often favored over binding contractual arrangements or compensatory measures as a mechanism for conserving biodiversity on private property. At the other end of the spectrum are the regulatory instruments, which in some countries regulate what private landowners may and may not do on their land (e.g., clearing native vegetation). The other categories of property rights and financial mechanisms are currently receiving a lot of attention in biodiversity conservation efforts – particularly those outside of protected areas.

Property rights mechanisms aim to support the management of these areas and their biodiversity and vary from relatively voluntary to contracted agreements between the conservation agency and the landowner(s). The most popular forms of agreement include management agreements and conservation easements. A management agreement is usually a short term (<30 year) legally binding contract setting out the use and management of the land and is an agreement between a landowner and a conservation agency (Crompton, 1990). Such agreements are currently being used in schemes like the Common Agricultural Policy of the European Union and conservation in the UK (Pence *et al.*, 2003). Management agreements are flexible and often coupled with financial mechanisms. A conservation easement transfers certain specified rights (e.g., development, timber harvesting, mining, etc.) from the landowner to a third party. These transfers can be attached to the property title deed and are either acquired by donation or purchase (Boyd *et al.*, 1999). In the USA conservation easements are used by private, nonprofit land trusts and by government agencies.

Financial mechanisms include a large range of instruments, which conservation organizations are putting into use in

Figure 5 This canopy walkway built in 1995 in Kakum National Park in Ghana has become a major attraction for tourists. Tourist numbers have grown from <1000 visitors per year in 1991 to almost 90,000 visitors in 2002, >80% of which are domestic. This has helped to create an effectively managed and sustainable national park (http://www.conservation.org/learn/culture/ecotourism/destinations/Pages/kakum_canopy_walkway.aspx) (Photo B Reyers).

motivating private and communal landowners to manage and conserve biodiversity on their land, and in helping landowners defer some of the costs associated with managing their land in this way. These instruments include grants, tax policies, commercialization, business instruments, and removal of perverse subsidies. Changes to tax policy have been quite pervasive and include changes to income tax, capital gains tax, rate relief as well as exemptions or deductions via property taxes, federal and state income taxes, and estate taxes (Fowler *et al.*, 1998). Examples of the commercialization of biodiversity and the business opportunities it offers can be seen in the growth of the wildlife industry and ecotourism sector (Figure 5) and more recently in the payments for ecosystem services arena. This growth has created many opportunities for private and communal land to contribute to biodiversity conservation objectives.

Private Conservation Areas

Conservationists have recently begun to realize the value of and need to strengthen the network of private conservation areas (Hale and Lamb, 1997; Knight, 1999; Langholz and Lassoie, 2001; Theobald *et al.*, 2000; Langholz and Krug, 2004). For example, Pence *et al.* (2003) and Gallo *et al.* (2009)

demonstrate the biodiversity contributions and cost savings of private conservation areas in South Africa. Pence *et al.* (2003) found that if private conservation areas were used in conjunction with statutory protected areas for conserving biodiversity, then the state would save 80% in acquisition costs. Private conservation areas are known by many other names, for example, private reserve, game reserve, private protected areas, but generally they meet four characteristics: (1) owned by freehold or long-term leasehold by a private investor(s) or syndicate; (2) funded and/or run by a private investor or syndicate; (3) managed for biodiversity and possibly for nature tourism, wildlife-based ventures or leisure; and (4) owned with the intent of preserving the land in a predominantly undeveloped state (Pasquini, 2007).

For the most part, these areas have been left out of conservation statistics, national conservation-planning frameworks, and until recently, generally out of academic research. However, the few studies performed show that thousands of private conservation area owners have demonstrated a willingness and capacity to conserve several million hectares of land (Langholz, 1996; Thackway and Olsson, 1999; Langholz and Lassoie, 2001; Chacon, 2005). Gallo *et al.* (2009) demonstrated that not only do private conservation areas significantly increase the achievement of biodiversity conservation targets (in their case target achievement tripled), but also that private land significantly complemented statutory conservation areas in the types of biomes, elevation classes, and threat status classes conserved. Private conservation areas were especially important in conserving productive lower-elevation habitat, and by association, endangered vegetation. In recognition of the contribution that private lands can make to conservation, several conservation agencies have begun to develop biodiversity stewardship programs to formalize and support the contribution of these areas to conservation (Box 3).

In growing and supporting private conservation areas both property rights and financial mechanisms have proved very important. While property rights have helped secure and enhance the contributions from private lands, financial instruments have proved very useful in bringing more landowners into conservation. The wildlife industry has played a substantial role in incentivizing landowners to switch from livestock grazing and other land-use practices to more conservation-aligned land-uses. As Young *et al.* (1996) point out, if clear and enforceable property rights and obligations are created for wildlife with commercial value, then it can be argued that an incentive (for those holding the property rights) will exist to maintain the species and their habitats. But as Scholes *et al.* (2008) argue, even in the absence of clear legal mechanisms, the incentive (financial and cultural) to switch to wildlife-associated land-use is large.

While in many cases hunting was a major trigger of the conversion of uneconomic livestock farms into mixed or wildlife-only farms, later it was 'nonconsumptive' uses such as recreational wildlife viewing, which took over as the major driver. The large expansion of foreign tourism into Africa and other popular wildlife areas has also played a role in maintaining the growth of this sector. Table 2 below from Scholes *et al.* (2008) provides some indications of the contribution of private wildlife reserves to the numbers of wildlife species in

Namibia. Scholes *et al.* (2008) estimate that in South Africa state-owned protected areas constituted 6% of the land area while the estimate of private wildlife ranches amounts to about 14%.

At a global level, wildlife and nature-based tourism has become the leading foreign exchange earner in several countries (Fillion *et al.*, 1992; The Ecotourism Society, 1998). These studies suggest that between 40% and 60% of international tourists were nature tourists, and that 20–40% of these were wildlife-related tourists. The Ecotourism Society (1998) further suggests that in 1994 there were between 106 million and 211 million wildlife-related tourists worldwide.

Community-Based Natural Resource Management

Another approach to biodiversity conservation outside of protected areas is the communal management of natural resources. The Community-Based Natural Resources Management (CBNRM) approach focuses on the collective management of ecosystems to improve human well-being. It aims to devolve authority for ecosystem management to the local (community) level, thereby empowering communities to manage their own resources without permanently damaging, depleting, or degrading them (Fabricius and Collins, 2007; Roe *et al.*, 2006).

A good number of reviews of CBNRM are critical of the input requirements and costs versus the household level benefits to community members and the benefits to conservation, as well as the high frequency of collapse (Shackleton *et al.*, 2002; Fabricius, 2004; Magome and Fabricius, 2004). Fabricius and Collins (2007) point out that because most CBNRM initiatives are in impoverished, remote rural areas, where human capital (skills

and education), financial capital and physical capital (infrastructure and services), are in short supply, CBNRM initiatives, and especially the institutions that are critical to CBNRM's functioning (Agrawal, 2001), are vulnerable to external change like conflicts, climate change, and political change.

In Southern Africa there has been a substantial investment in trying to address some of these shortcomings by making

Table 2 Some trends relating to livestock and wildlife on private land in Namibia

<i>Changes over time</i>				
Livestock				
<i>Livestock populations</i>				
Year	1971	1981	1991	2001

Box 3 Biodiversity stewardship as a means of growing a nation's conservation estate

In many parts of the world the concept of stewardship is helping conservation agencies in working with landowners outside of formal protected areas. Stewardship is basically defined as: "The wise use, management and protection of that which has been entrusted to you as a landowner or is rightfully yours". Biodiversity stewardship is therefore "the practice of effectively managing land-use outside the existing state-managed protected area system to ensure that natural systems, biodiversity and the ecosystem services they provide are maintained and enhanced for present and future generations" (www.stewardship.co.za). In South Africa, if a willing landowner has land in an area of high conservation-value, then an agreement between the land owner and government can be signed and the degree of protection is determined. This degree of protection is determined by national legislation and can include:

- Conservancies
- Protected Environments
- Nature Reserves
- Parts of land to be protected under biodiversity stewardship agreements

A nature reserve is the highest protection possible under this scheme, and the requirements are the most stringent. The Conservancy option is the least onerous on the landowner, and is also the lowest protection. These agreements:

- require commitment from landowners;
- provide long-term security to biodiversity;
- require that sites be managed for conservation;
- require monitoring and auditing of sites; and
- reward landowners for committing land for the public good.

In Australia, Environmental Stewardship uses competitive auctions where private land managers can bid to participate in protecting, rehabilitating, and improving particular ecological communities. Successful land managers are contracted to manage these communities on their land and can receive funding for activities (<http://www.nrm.gov.au/stewardship/index.html>).

management information available to communities. For example, the Namibian Association of Community-Based Natural Resource Management Support Organizations (NACSO) is an association comprising 15 Non-Government Organizations (NGOs) and the University of Namibia, which aims to provide quality services to rural communities seeking to manage and utilize their natural resources in a sustainable manner (<http://www.nacso.org.na/>). There are similar programs in Botswana (<http://www.cbnrm.bw/>) and in the region broadly (<http://sacfnr.org/>).

Many remain positive about the contribution and need for the devolution of natural resource management to communities. CBNRM's greatest contribution to biodiversity conservation is likely to be through management of habitats and ecosystems in a manner that makes them suitable for the maintenance of wildlife populations. A review of CBNRM in Southern Africa (Nunes *et al.*, 2008) found evidence of the positive impacts of CBNRM on wildlife habitats and populations. For example, in Zimbabwe, 12 rural district councils maintain wildlife habitats ranging from 500 to 5000 km² (Roe *et al.*, 2006). In Namibia CBNRM was shown to have contributed to the recovery of wildlife populations, especially large mammals, across large parts of the north (NACSO, 2004). Furthermore, between 1993 and 2003, approximately 3000 head of mixed plains game species had been successfully reintroduced in communal conservancies in this country (Roe *et al.*, 2006). In South Africa a number of communities granted legal ownership of land currently under conservation management during the national land restitution process, have chosen to maintain these conservation areas (Grossman and Holden, 2007). However, beyond these few studies, true impacts are poorly quantified and are largely assumed based on changes in land management practices. This makes definitive conclusions on the contributions and costs of these areas currently not possible.

In a review of CBNRM in Southern Africa, Fabricius and Collins (2007) list 11 strategies necessary for increasing the success of these initiatives ranging from an improved understanding of the system to be managed; the involvement of local organizations with a clear vision; good planning, monitoring and rule enforcement; management, incentives and financial capacity; and supportive legal frameworks.

While many of these strategies link to the financial, legal, motivational, and other instruments listed above for growing the contribution of areas outside of protected areas, there are some unique challenges when it comes to applying these instruments in communal areas. What is often termed communal or customary tenure is a mix of colonial and customary law and is "the joint creation of colonial officials and African leaders... a reflection of the [then] contemporary situation" (Colson, 1971). Peters (2007) argues that the formation of customary law (as it applies to communal land tenure) in communal areas was shaped by colonial thinking and often served state, European, and elitist African interests. Though individuals do not have private tenure, this does not mean that individuals do not have defined rights to resources. These tenure rights are complex and in many instances can be considered as nested or layered, with different individuals having different rights (Peters, 2007). This makes the application of motivational, legal, or financial instruments quite complex as opposed to the case of a single private owner for whom they were designed.

Payments for Ecosystem Services

While many of the approaches listed above have the potential to contribute substantially to the conservation of biodiversity outside of protected areas, this potential is often constrained by the lack of financial incentives for landowners to set aside land for conservation. Putting private land into conservation can often incur management costs, as well as limit or even lose income from other production opportunities (Frazee *et al.*, 2003). While in some cases conservation agencies can provide some assistance in reducing these costs, for example, through providing management assistance, or through other financial mechanisms like tax rebates, this is often not enough. There has been a recent emergence of other approaches that attempt to grow the range and amount of financial incentives (Fowler *et al.*, 1998). Chief amongst these approaches are payment for ecosystem service (PES) schemes, which compensate individuals or communities for undertaking actions that increase the provision of ecosystem services. Ecosystem services are the benefits that people receive from ecosystems, including flood protection, carbon sequestration, and water flow regulation and purification (MA, 2005). In many cases, land that is managed to conserve biodiversity will also provide many ecosystem services and thus landowners could potentially receive payment for the ecosystem services their land provides (but see Redford and Adams, 2009). As Jack *et al.* (2007) highlight, PES schemes, because they incentivize behavioral change, can be seen as part of the broader class of incentive- or market-based mechanisms. These schemes can bring more private and public funding to conservation, thus expanding available budgets (Jenkins *et al.*, 2005; Turpie *et al.*, 2008).

Working Lands and Waters

Given that agriculture (including crop cultivation, forestry, and aquaculture) now accounts for the greatest proportion of the earth's land surface (~40%), uses most of the world's water (66%) and continues to expand (Foley *et al.*, 2005; Scanlon *et al.*, 2007), a better understanding and engagement with the agriculture-conservation interface is clearly required (Matson *et al.*, 1997). Agricultural activities have had a widespread impact on a variety of habitats resulting in a loss of biodiversity across many taxa (Benton *et al.*, 2003), and simultaneously affecting the production of ecosystem services through ecosystem simplification (Björklund *et al.*, 1999; Tilman *et al.*, 2002; Gordon *et al.*, 2010). Agriculture has substantially modified the global hydrological cycle in terms of both water quality and quantity (Gordon *et al.*, 2010).

In the past 40–50 years agriculture has become a technical process, in which outputs are dependent on external inputs such as pesticides, fertilizer, and fossil-fuel driven technology (Altieri, 1999; Björklund *et al.*, 1999; Edwards and Abivardi, 1998; Pretty, 1995). Ecological processes, which help to promote fertility or control pests and disease, have generally not been considered important in maintaining agricultural production (Edwards and Abivardi, 1998). Much agriculture is therefore currently sitting in the top left hand corner of Figure 4 with a focus on production uses to the exclusion of any contributions to biodiversity conservation.

Determining the links, potential trade-offs and synergies between conservation and agriculture is now seen as crucial in formulating future conservation strategies, stemming large-scale biodiversity loss, ensuring ecosystem service flows and moving agricultural lands into the center of the framework – as working lands producing food, fiber and other materials, but not to the exclusion of biodiversity. From the current evidence it appears that there are a number of changes necessary in the way agriculture is carried out, if food and fiber security are to be achieved without negative impacts to biodiversity and ecosystem services. The chief of these changes are agricultural management practices and the current focus on monocropping.

Management Practices

While the rate of agricultural expansion has slowed in the past three decades, yields have increased dramatically and have outpaced global human population growth resulting in more food available per capita today than in recent human history (MA, 2005). This progress has been made possible by the use of high-yielding crop varieties, chemical inputs, and a focus on monoculture, often on land already under agricultural management (Matson *et al.*, 1997). Intensification has substantial impacts at all scales including impacts on water quantity, water quality, biodiversity loss, and soil quality. Some of these declines in biodiversity and ecosystem services are of importance to agriculture itself and can have negative effects on agricultural productivity, thereby undermining the long-term sustainability of agricultural intensification. Soil salinization is an example where the regulating ecosystem service (water table regulation) is compromised in a way that feeds back on agriculture (Gordon *et al.*, 2010). This then results in either a collapse of the agricultural system, or as is most often the case, more technological and external inputs in the system, for example, more fertilizers, irrigation, or more pesticides, further exacerbating the problem.

In a recently published review of the impacts of agricultural activities, Rockström *et al.* (2009) point to several “planetary boundaries” or global thresholds, towards which agriculture has forced the global Earth system. Many ecosystems of Earth react in a nonlinear, often abrupt, way, and are particularly sensitive around threshold levels of certain key variables. If these thresholds are crossed, then important subsystems, such as a monsoon system, could shift into a new state, often with deleterious or potentially even disastrous consequences for humans. These boundaries include climate change; rate of biodiversity loss; interference with the nitrogen and phosphorus cycles; global freshwater use; change in land-use; chemical pollution; stratospheric ozone depletion; ocean acidification; and atmospheric aerosol loading nitrogen levels. Of these nine the first six are inextricably linked to agricultural practices.

While agricultural practices have resulted in reductions in biodiversity and ecosystem services, it is also evident that some agricultural ecosystems can be critical repositories of biodiversity, and that the particular type of agricultural practice is a determinant of the biodiversity within that ecosystem (Perfecto *et al.*, 2003; Moguel and Toledo, 1999; Donald,

2004). This biodiversity includes both planned biodiversity (the species of importance to agricultural production, e.g., food crops) and associated biodiversity (Vandermeer *et al.*, 2002). Intensification of agriculture is taken to be the transition from ecosystems with high planned biodiversity to low planned biodiversity and an increase in the use of agrochemicals and machinery (Vandermeer *et al.*, 2002; Perfecto *et al.*, 2003; Perfecto and Vandermeer, 2010). In many cases the application of agrochemicals is to substitute the functions or ecosystem services of some of the associated biodiversity that is eliminated. The impacts on associated biodiversity are less certain and can either start off slowly and increase as intensification increases, or disappear immediately as intensification starts. This uncertainty lies behind much of the debate between intensification versus extensification.

Currently there is a confusing array of options to explore and little consensus on which management practices are best. Some suggest intensification in high-yield areas will conserve more biodiversity in the remaining areas (Green *et al.*, 2005), others suggest low-intensity agriculture over wider areas is better for biodiversity (Donald, 2004). For more discussion on this debate see Perfecto and Vandermeer (2008). In essence this debate rests on the assumption that more productive systems are worse for biodiversity but that is not always the case. Bengtsson *et al.* (2005) demonstrate that organic/agroecological production systems can be just as productive in terms of crop yields but better for biodiversity. Perfecto and Vandermeer (2008) conclude that “it is not only the conversion from a native habitat to agriculture that matters for biodiversity conservation, but also the conversion of agriculture from a biodiversity-friendly type to a biodiversity-unfriendly type that accounts for most biodiversity loss within agricultural landscapes”.

Biodiversity-friendly Agriculture

Biodiversity-friendly agricultural practices are basically those that are based on the principles of ecological design. Matson *et al.* (1997) suggest that “ecologically designed agricultural systems that reintegrate features of traditional agricultural knowledge and add new ecological knowledge into the intensification process can contribute to meeting this challenge” (of increased production while avoiding the side effects on biodiversity and other ecosystem services). Such management approaches include integrated nutrient–organic matter management, precision agriculture and pest management approaches. For example, integrated pest management through host resistance and biological control could replace the damaging use of pesticides. No-till agriculture and riparian and wetland restoration are all examples of the recent development of ecologically informed management practices, which can help promote production in agricultural systems while limiting the damaging effects on nontarget species and systems.

The costs and benefits of biodiversity-friendly management practices are not yet clear. But in the case of high costs, the range of financial and other instruments (*see* Living Lands and Waters) could be useful in addressing some costs to

Box 4 South Africa's biodiversity and wine initiative

http://www.wwf.org.za/what_we_do/outstanding_places/fynbos/biodiversity___wine_initiative/

The biodiversity and wine initiative (BWI), which emerged from intense cooperation and collaboration between the South African wine industry and the conservation sector, is a good example of the successes which can be achieved in the area of biodiversity-friendly agriculture. The central tenet of this initiative is to prevent the further loss of biodiversity in the areas actively engaged in wine production by increasing the area within these regions under conservation (Kotze, 2008). This initiative has introduced a stewardship system where producers who establish a contract nature reserve qualify for between 80% and 100% tax rebates. To date a total of 116 farmers formally participate in the BWI (Kotze, 2008). The total area of land conserved by these landholders as a result of this program is 70,411 ha of pristine natural vegetation, incorporating threatened lowland Fynbos, Renosterveld, and Succulent Karoo (Kotze, 2008). This is approximately equivalent to 70% of the footprint of the wine industry in the Western Cape. This initiative has also developed biodiversity best practice guidelines for the wine industry. Guidelines are aimed at changing practices within the industry to enhance suitability of vineyards for biodiversity conservation, for example, guidelines for buffer areas around watercourses, clearing of invasive alien plants, indigenous wildlife introductions, and fire management. The initiative assists farmers in assessing the conservation value of their land and implementing these guidelines.

The opportunities for certification and product differentiation based on conserved biodiversity features are clear, and the BWI has developed a two-pronged approach in this regard. First, the BWI markets itself in conjunction with the farms that are members of this initiative, advertising the farms and their conservation credentials widely. Second, the BWI in association with their stakeholders and members have developed an 'on bottle' labeling system, which allows consumers to easily identify 'conservation wines,' BWI members, and their conservation contributions. Close cooperation and on-farm biodiversity assessments by the BWI ecologists also provide landholders with biodiversity information that can be used in their labeling and marketing strategies.

The initiative is currently undertaking a spatial review assessing the contribution of conserved areas to meeting conservation targets within the broader Cape Floristic Region. This will focus future efforts in prioritizing conservation and stewardship efforts (Kotze, 2008). The BWI has assisted the wine industry in creating and implementing a sustainable production strategy, and the biodiversity guidelines prescribed as part of the industry's Integrated Production of Wine Scheme, have been accepted as part of the international sustainable production guidelines for the global wine industry (Kotze, 2008). The BWI is clearly making great strides and serves as a model for other agriculture-conservation partnerships. Their experiences are already guiding the initiation and development of other schemes including potato and *rooibos* tea farming, as well as the production of honey (Petersen, 2007).

landowners, but also in encouraging consumers to pay more for these products. Certification schemes, labeling, niche markets, monitoring, and evaluation are all areas requiring improved understanding and investment if biodiversity-friendly agriculture is to have the desired impact (O'Farrell *et al.*, 2008). **Box 4** showcases an example of the development of biodiversity-friendly viticulture through a collaboration between the wine industry and the conservation sector in South Africa.

Multifunctional Landscapes

In addition to management practices, which reduce the impact of intensification processes on biodiversity and ecosystem services, there is a need to adopt a more integrated approach when considering food/fiber production or biodiversity conservation in agricultural lands. As Matson *et al.* (1997) point out, one of the main flaws of the traditional practices of intensification is monocropping, which can ultimately undermine productivity

in these areas. Similarly one of the main flaws of traditional approaches to biodiversity conservation is the focus on alpha (local) diversity rather than beta (species turnover across patches in a landscape) diversity, which can ultimately lead to extinctions if species are prevented from moving between habitat patches. As [Perfecto and Vandermeer \(2008\)](#) point out, farming systems, if managed as diverse, organic agroecosystems, can actually help conserve beta diversity by providing the matrix through which species can move. This shift in thinking to a multifunctional diverse landscape has heralded exciting opportunities for conservation in agricultural systems.

The notion of landscape multifunctionality moves away from the traditional management of a single-function landscape manipulated to, for example, either produce food or serve as a recreation area to a landscape offering multiple environmental, social, and economic benefits ([de Groot, 2006](#); [Lovell and Johnston, 2009](#); [Wiggering et al., 2006](#)). The design ([Nassauer and Opdam, 2008](#)) and management of landscapes with multiple goals including sustainable food production, biodiversity conservation, water production, and job creation holds the potential to improve both production and ecological functions and therefore the longer-term resilience or sustainability of the landscape ([McNeely and Scherr, 2003](#)). This is an appealing prospect and will require the consideration of the inherent contributions of various landscape features to multiple goals ([Lovell and Johnston, 2009](#)). Furthermore, it requires a thorough understanding of synergies and trade-offs between multiple goals ([De Fries et al., 2004](#); [Reyers et al., 2009](#); [Rodríguez et al., 2006](#)), a good knowledge of the social context in terms of stakeholders, institutions, and incentives ([Cowling et al., 2008](#)) and the ability to transfer all of this knowledge into the design and establishment of multifunctional landscapes ([Nassauer and Opdam, 2008](#)).

In many ways the multifunctional landscape approach embraces the entire spectrum in [Figure 4](#) in that it supports areas devoted to multiple objectives through a clear regional plan, which takes into account the contribution all areas make to the development and conservation goals and arranges them in the landscape in a way that ensures achievement of multiple societal goals while taking into account interconnections and trade-offs between goals (e.g., [Polasky et al., 2008](#); [Lovell and Johnston, 2009](#); [O'Farrell et al., 2010](#)).

Multiple Uses

In many cases examples of living and working lands approaches to conservation include multiple land-uses and tenures in their design and allow for a network of areas and corridors managed for varying uses and conservation goals. These networks can even be associated with formal protected areas in the region.

Biosphere Reserves

Biosphere reserves are sites established by countries and recognized under UNESCO's Man and the Biosphere (MAB) Program to promote sustainable development by combining core protected areas with zones where sustainable development

is fostered. Biosphere reserves aim to achieve integrated management of land, fresh and marine waters and living resources by putting in place bioregional planning schemes based on integrating conservation into development through appropriate zoning of core, buffer, and transition zones. There are currently 580 such sites in the world.

Conservancies

There are several other kinds of conservation approach, which mimic the approach of biosphere reserves, but are usually smaller and more local in their management.

There are many names by which these multiple use conservation areas are known including conservancy or mega-conservancy. But in essence they are a collection of mostly agricultural properties, which are cooperatively managed under a single management plan, bound with a voluntary agreement between the landowners and the state. They promote the conservation of certain natural resources, the extension of the regional conservation area network, and increased public awareness regarding the wise management of the natural environment.

They aim to achieve conservation goals over a contiguous patchwork of properties of various tenures and land uses, maximizing landscape heterogeneity and the management of capital flows (e.g., natural, financial, social) ([Knight and Cowling, 2003](#)). This can be achieved only if the component properties are managed in a coordinated, cooperative, and integrated way ([Pierce et al., 2005](#)). These areas ideally cover important sensitive natural areas so as to ensure that landscape-scale ecological processes, such as the movement of animals and water flows, function effectively. This better ensures that the goals of agricultural production, water use, and biodiversity conservation can be aligned and achieved in a cooperative way. The result is more viable environmental, social, and economic systems – or in other words, living landscapes ([Figure 6](#)).

As [Knight and Cowling \(2003\)](#) point out the management of natural resources and biodiversity in conservancies is usually informed by integrated instruments e.g., integrated catchment plans, integrated development plans. These approaches ensure shared goals across these resource management fields in order to ensure that objectives are aligned and integrated. Integrated management requires that the condition of resources is regularly monitored and evaluated and new information from this process is used for refining land management activities. A wide range of instruments are used to achieve such conservancy goals and to encourage participation by stakeholders. Examples of instruments include tenure (e.g., protected areas), zoning categories, tax relief, legislation, land-use policy, market incentives, and conservation and land-use programs.

The Contribution of Living and Working Lands to Conservation

As many conservationists would point out: land managed for wildlife or for tourism or even for grazing is not synonymous with biodiversity conservation. Many have expressed concerns about these activities and their negative impacts on

Figure 6 Hypothetical conservancy map showing multiple land uses possible within such an area. Reproduced from Knight AT and Cowling RM (2003) *The Megaconservancy Network concept: 'Keeping people on the Land in Living Landscapes'*, Terrestrial Ecology Research Unit Report No. 45. University of Port Elizabeth.

biodiversity (e.g., Dalal-Clayton *et al.*, 1997) as well as their lack of security as a means for conservation. But while these concerns might be true in some cases, they also apply to some formal protected areas where processes like land reform, land development, and the degazetting of protected areas threatens biodiversity and the security of these areas (Brandon *et al.*, 1998; Bruner *et al.*, 2001). The benefits of such areas may also outweigh their supposed disadvantages as is evidenced by the contribution they can make to biodiversity conservation, often conserving biodiversity that is not protected in formal protected areas. Gallo *et al.* (2009) found that while private conservation areas were more degraded and transformed than formal protected areas, these minor shortcomings were offset by the overall representation and complementarity benefits provided by private areas. Further, in regions with poor enforcement of protected area boundaries (e.g., Liu *et al.*, 2001), private and communal conservation areas (which are enforced by the landowner themselves) may actually be more pristine than other protected areas, as well as helping constrained conservation budgets do more with less (e.g., Yuan *et al.*, 2008). Several of the motivational and educational instruments can also help contribute to improving the longevity of

the contribution made by private and communal protected areas (Chacon, 2005; Winter *et al.*, 2005).

It would appear that the contribution of private and communal living lands to conservation is potentially large, not only in the extent of land and water, people and resources it could offer to conservation, but also in the complement of biodiversity found in these areas usually absent from state owned and formal protected areas. But in order to realize this potential there is a need for more information on these areas where monitoring and evaluation are currently rare. This information would allow for the assessment of their contribution to biodiversity conservation, as well as other development goals, and for improved learning on the effects of a wide variety of management practices on biodiversity. All reviews highlight the need for improvements in the reliability of information on the location, extent, and management practices on private and communal land. There is a further need to ensure that information and necessary skills are made available to the managers of biodiversity on private and communal land to improve the track record of these areas in the arena of biodiversity conservation. Finally, conservationists need to engage more with the wide range of instruments

available for extending the conservation effort outside of protected areas and begin to engage with other disciplines that better understand issues like incentives, motivation, and tax reform.

In distilling what appears to be critical in ensuring the success of these living and working lands, a few key ingredients emerge from a review of the literature (O'Farrell *et al.*, 2008; Knight and Cowling, 2003; Donaldson, 2002; Turpie *et al.*, 2008):

- A vibrant conservation sector with a strategically located champion integrally linked to the emerging initiative.
- A strong collaboration between the conservation and production (e.g., agriculture, wildlife, or forestry) sectors.
- Knowledge dissemination and extension services to landowners to promote the understanding of trade-offs associated with management decisions.
- A critical mass of support for the initiative coupled to the establishment of an 'anchor tenant/s' whom the initiative can be built around.
- Clearly perceived benefits from the maintenance of biodiversity, which outweigh the costs of conserving biodiversity.
- Enabling mechanisms such as subsidies, extension services, and research. These have been found to often be more effective at achieving a change in behavior compared with legal instruments.
- Clearly distinguishable products emerging from the intervention or initiative, for example, labeling or certification.
- Well-assessed market identification and public/consumer demand.
- Restoration programs (often partnered with job creation programs) which focus on biodiversity and development targets.
- A sound legislative and policy framework (essential, but by itself not enough).
- Promotion of incentives, tourism, and other biodiversity-based business opportunities as a means to offset costs.
- Monitoring and evaluation incorporated into interventions, and geared toward assessing and evaluating both the biological and socioeconomic implications of interventions at appropriate stages.

Glossary

Avoidance Measures taken to prevent impacts from occurring in the first place—for instance, by changing or adjusting the development project's location or the scope, nature, and timing of its activities.

Biodiversity offsets Measurable conservation outcomes resulting from actions designed to compensate for significant residual adverse biodiversity impacts arising from project development after appropriate prevention and mitigation measures have been taken. The goal is to achieve no net loss and preferably a net gain of biodiversity on the ground with respect to species composition, habitat structure, and ecosystem function.

Environmental impact assessment (EIA) A formalized process, including public consultation, in which all relevant environmental consequences of a project are identified and assessed before authorization is given. The process of identifying, predicting, evaluating and mitigating the biophysical, social, and other relevant effects of development proposals prior to major decisions being taken and commitments made.

Footprint The area of land or water covered or affected by a project. This can include the direct physical coverage (i.e., the area on which the project physically stands) and the area indirectly affected by the project (i.e., the area affected by disturbances such as noise that directly emanate from the project).

Minimization Minimizing impacts by limiting the degree or magnitude of the development action and its implementation in a manner consistent with conservation goals.

Mitigation Measures that aim to reduce impacts to the point where they have no adverse effects.

Mitigation hierarchy Hierarchy that may include avoidance, minimization, restoration, or offset. In *avoidance*, to completely avoid impacts on certain components of biodiversity, measures are taken to avoid creating impacts from the outset, such as careful spatial or temporal placement of elements of infrastructure. In *minimization*, as far as is practically feasible, measures are taken to reduce the duration, intensity, and/or extent of impacts that cannot be completely avoided. In *restoration*, measures are taken to rehabilitate degraded ecosystems or

restore cleared ecosystems after exposure to impacts that cannot be completely avoided and/or minimized. In *offset*, achieve no net loss or a net gain of biodiversity, measures are taken to compensate for any residual significant adverse impacts that cannot be avoided, minimized, and/or rehabilitated or restored. Offsets can take the form of positive management interventions such as restoration of degraded habitat, arrested degradation or averted risk, or protecting areas where there is imminent or projected loss of biodiversity.

No net loss Target for a development project in which the impacts on biodiversity caused by the project are balanced or outweighed by measures taken to avoid and minimize the project's impacts, to undertake on-site restoration, and finally to offset the residual impacts so that no loss remains. Where the gain exceeds the loss, the term *net gain* may be used instead of *no net loss*. No net loss (or net gain) of biodiversity is a policy goal in several countries, and is also the goal of voluntary biodiversity offsets.

Offset activities The set of activities identified to achieve no net loss or a net gain of biodiversity in the specific context of the development project concerned. They can involve a mixture of activities, including averting risk and undertaking positive management interventions. In *averting risk*, areas of biodiversity in which there is imminent or projected loss of that biodiversity are protected; agreements such as contracts or covenants with individuals are struck in which they forgo the right to convert habitat in the future in return for payment or other benefits received now. In *undertaking positive management interventions* to restore an area or stop degradation, the conservation status of an area of land is improved by restoring habitats or ecosystems and reintroducing native species. Where proven methods exist for successful reconstruction or creation of ecosystems these may be undertaken. In other instances, a project might reduce or remove current threats or pressures by, for instance, introducing alternative sustainable livelihoods or substitute materials.

Residual impact The remaining adverse impact on biodiversity after appropriate avoidance, minimization, and restoration actions have been taken according to the mitigation hierarchy.

Chapter Outline

- The world is changing more rapidly each day. Fast-paced development threatens some of our most cherished lands, waterways, and wildlife.
- Over the next two decades, there will be even more pressure to convert and develop our lands and waters to provide food, energy, transportation, and housing for a growing and hungry world.
- Achieving conservation goals will require a more integrated vision of development and conservation.
- Here we outline an innovative science-based approach called Development by Design (DbD) to help guide more sustainable development.
- DbD brings together conservation and mitigation planning to help reduce conflicts between development and conservation goals, improve the effectiveness of mitigation (to avoid, minimize, restore, and offset impacts), and deliver more sustainable outcomes for the development of natural resources.
- DbD seeks to achieve a net gain for both development and environment.

Introduction

The world is on the cusp of a sea change. World population is projected to grow to more than 9 billion by 2050 with a rapid pace of development in order to meet the growing demands for food, water, energy, minerals, and other resources. At the same time, most of the world's people don't care about biodiversity, and most don't think of nature conservation as essential to meet their basic needs. People want food and shelter, safety and security, and an opportunity to improve their livelihoods. And they see the use of natural resources as a way to further those objectives. Achieving conservation goals will require a more integrated vision of development and conservation. The conservation community needs to recognize that not everyone wants to set aside the world into a series of protected areas or parks for the sole purpose of wildlife conservation. The importance of economic development for improving human well-being means that society will likely choose to value development over conservation if we continue to present it as an either-or option.

In this chapter, we put forward a four-step framework called DbD that supports development *and* conservation goals by harnessing advances in conservation and mitigation planning. Then to illustrate how the DbD framework can advance truly sustainable outcomes, we apply it retroactively to the Wyoming Basins Ecoregion (WBE), a landscape rich in both energy resources and conservation values. We examine the additional conservation activities that would have been implemented if the framework had been applied, and discuss how taking these steps in the past could have reduced the need for current Endangered Species Act restrictions on development, putting the region in a better position to meet today's and perhaps tomorrow's energy development and conservation needs.

Over the next two decades, energy and mining companies will invest unprecedented sums—far more than \$20

trillion—in projects around the world from Madagascar to Mongolia. Rapidly developing countries like China and Brazil are making trillion dollar investments in infrastructure. In most cases, the environmental mitigation process for addressing impacts of development projects is ad hoc, opaque, and insufficient, failing to deliver effective outcomes for biodiversity conservation (Environmental Defense, 1999; National Research Council, 2001; Environmental Law Institute, 2002; Federal Interagency Mitigation Workgroup, 2002; Brown, 2006; Gibbons, and Lindenmayer, 2007; Thorne *et al.*, 2009; McKenney and Kiesecker, 2010). Mitigation offers the opportunity to minimize the impacts of development through application of the mitigation hierarchy: avoid, minimize, restore, and offset (Council on Environmental Quality, 2000). Mitigation also represents the best global opportunity for mobilizing billions of dollars for conservation. When compensatory mitigation (also known as *biodiversity offsets*) is a normal part of project costs, the level of funding available for conservation dwarfs other funding sources by many multiples. Consider US wetland mitigation, where no net loss goals and the use of wetland offsets and banks generates \$3 billion in funding annually (Environmental Law Institute, 2007). Compare this figure with federal appropriations of about \$300 million annually for the US Land and Water Conservation Fund or \$2.5 billion annually for the entire US National Park System. Likewise, in Wyoming \$36 million was established as a mitigation fund for a single gas field and \$24.5 million for another. Compare these figures with the \$4 million available annually for wildlife conservation from the Wyoming Wildlife and Natural Resource Trust (Kiesecker *et al.*, 2009).

But in the US and around the world, there are many problems with how mitigation is applied. Traditionally, mitigation has been carried out on a project-by-project basis; specific measures are implemented to mitigate project impacts at a site, usually on or adjacent to the impact site. But with conservation goals defined at a landscape level, applying the mitigation hierarchy on a project-by-project basis, often at small spatial extents, underestimates the cumulative impacts of multiple current or future development projects and undermines the hierarchy's purpose and utility (Figure 1). In our opinion, the way mitigation is currently applied does not capture cumulative impacts associated with development. It does not provide a structured decision-making framework to determine when projects can proceed or should be avoided, and it does not harness the full potential of offsets (conservation actions applied away from the development site). There is a strong need to improve the mitigation process with better science and more transparency to address key challenges, including how best to ensure conformance with the mitigation hierarchy, identify the most environmentally preferable offsets within a landscape context, and determine appropriate mitigation replacement ratios. For these reasons, we think an overhaul of existing mitigation practices is in order to more effectively address expected development in the coming years. This is the ideal time for this kind of overhaul. Around the world, there are now 45 compensatory mitigation programs for biodiversity impacts, with another 27 programs in development (Madsen *et al.*, 2010). Major financial institutions are requiring infrastructure projects to meet performance standards that include the full sweep of mitigation, from avoiding

Figure 1 Map of mineral leases in Mongolia. Top panel shows leases of a single company currently moving from exploration to development. As it develops its leases, it will negotiate with the Mongolian government for infrastructure needs as well as actions necessary for mitigation. This company has a corporate policy of net gain for biodiversity associated with its development activities. Bottom panel shows all leases currently under either exploration or development. Attempts by any single leaseholder to develop necessary infrastructure or achieve positive mitigation outcomes will be difficult without consideration of cumulative impacts. Inset map shows the location of the study area.

impacts to compensatory actions (International Finance Corporation, 2012). And leading companies increasingly see this as a normal cost of doing business (Rio Tinto, 2004).

The Framework for Development by Design

The four-step DbD framework has been developed to address key deficiencies in mitigation and to mesh with existing

regulatory approaches. It supports a more comprehensive approach to mitigation planning applied at two distinct spatial scales. First, it can be applied at a *landscape, watershed, or seascape level* to determine conservation priorities in the context of multiple objectives, to assess potential cumulative impacts, to identify possible conflicts between objectives, to assess the compatibility (or incompatibility) of impacts with conservation goals, and to evaluate opportunities for sustainable outcomes (steps 1 and 2). Second, it can be applied at a

project or site level to assess site-level impacts, to design a mitigation strategy involving offsets to address impacts, and to measure progress toward fully compensating for impacts (steps 3 and 4).

The key components of DbD are as follow.

1. *Setting landscape conservation priorities:* Where are the highest priority areas for conservation, ecosystem services, and other values in the region?
2. *Making mitigation decisions consistent with landscape planning:* How will projected development affect the region? Given expected impacts, what are the best options to support sustainability?
3. *Determine residual impacts and select optimal offset portfolio:* Where impacts occur, how can compensating mitigation (i.e., offsets) best deliver values ecologically and functionally equivalent to those lost, be located at an acceptable proximity from the impact site, and contribute to landscape conservation goals?
4. *Estimating offset contribution and progress toward goals:* To what extent will mitigation actions support sustainable outcomes? To what extent will offsets compensate for impacts to achieve a net gain or no net loss goal? Which offsets will provide the best conservation return on investment—highest conservation value at least cost and risk?

Step 1: Setting Landscape Conservation Priorities

Landscape-level conservation planning has a rich history (Pressey *et al.*, 1997; Ball and Possingham, 2000; Pressey and Bottrill, 2008), and our goal here is not an exhaustive review on the methods behind or importance of conservation planning but rather to illustrate how it can be utilized to direct mitigation. Conservation planning, particularly ecoregional assessments (e.g., Groves, 2003), provides the structure to ensure that mitigation is consistent with conservation goals, which often include the maintenance of large and resilient ecosystems to support both healthy wildlife habitats and human communities. Blending the mitigation hierarchy with landscape planning offers distinct advantages over the traditional project-by-project approach because it considers the cumulative impacts of both current and projected development, provides regional context to better guide which step of the mitigation hierarchy should be applied (i.e., avoidance vs. offsets), and offers increased flexibility for choosing offsets that can maximize conservation return by providing funding for the most threatened ecosystems or species.

Landscape-level conservation planning is the process of locating and configuring areas that can be managed to maintain viability of biodiversity and other natural features (Pressey and Bottrill, 2008). The resulting conservation plan is intended to clearly articulate a vision that incorporates the full range of ecosystem services and biological features, their distribution, and the minimum needs of each to persist in the long term (e.g., Tear *et al.*, 2005). Creation of the vision depends on the active involvement of host governments, experts of many disciplines, development organizations, and citizens in the region. A conservation portfolio of priority sites, the end

product of conservation planning, is a selected set of areas that represents the full distribution and diversity of the biological features the plan attempts to conserve (e.g., Noss *et al.*, 2002). Often plans use an optimization approach automated with spatial analysis tools to meet the minimum viability needs of each biological target yet minimize the amount of area selected (Pressey *et al.*, 1997; Ball and Possingham, 2000). Optimization tools provide flexibility for reconfiguring conservation plans in the context of future development scenarios (Kiesecker *et al.*, 2010; Saenz *et al.*, 2010; Kiesecker *et al.*, 2011a; Heiner *et al.*, 2011). To date, conservation plans (i.e., ecoregional assessments) have been conducted in many places around the world, providing opportunities to harness these data to implement DbD (Dinerstein *et al.*, 2000; Groves, 2003). In places where conservation plans have yet to be completed, rapid assessments can be conducted in a manner that allows them to address the mitigation of future development in a time frame that is congruent with regulatory decision making (see Saenz *et al.*, 2010, and Heiner *et al.*, 2011, for examples).

Step 2: Making Mitigation Decisions Consistent with Landscape Planning

Development by Design entails analysis of conservation plans in the context of future development (i.e., Copeland *et al.*, 2009). Proposed projects, along with projected development activities (e.g., oil and gas, wind, solar, residential, agricultural conversion, and some types of mining development), can be mapped and assessed relative to existing conservation priorities or incorporated in the development of a new conservation plan (Kiesecker *et al.*, 2010; Saenz *et al.*, 2010; Heiner *et al.*, 2011). Whenever possible, development patterns should be designed within a framework that takes into account conservation goals for healthy ecosystems (see, e.g., Kiesecker *et al.*, 2011b). Under the DbD approach, overlap or conflicts between conservation priorities and development impacts can be addressed by a redrawing of the conservation portfolio to recapture habitat elsewhere in the study area to meet minimum viability needs of target species and ecological systems. However, if conservation goals cannot be met through redrawing of the conservation priorities, then development impacts would need to be minimized to the degree that biodiversity values are maintained or impacts must be avoided (Kiesecker *et al.*, 2010; Figure 2).

This approach offers important advantages over current approaches to mitigation. It provides an opportunity to avoid conflict between potential development and areas critical for biodiversity and ecosystem services, and it also provides the structure to guide decisions about which step in the mitigation hierarchy should be applied in response to proposed development (Figure 2). Whereas mitigation is often fraught with subjective and opaque decision making, applying science-based conservation planning through this framework provides a more transparent and credible basis for informing key issues: how compatible impacts are with conservation goals and what the opportunities are for moving beyond zero-sum development versus conservation conflicts. More broadly, by integrating conservation and development planning at a

Figure 2 Landscape-level Development by Design approach in Mongolia. Top panel shows initial conservation portfolio and existing mineral and petroleum leases. Middle panel shows areas of potential conflict with mineral and petroleum development and mitigation recommendation (avoid or offset) for conflict areas. Bottom panel shows conservation portfolio redesigned to minimize conflict with mineral and petroleum development. Inset map shows the location of the study area within Mongolia. For details, see Heiner M, Davaa G, Kiesecker J, *et al.* (2011) *Identifying Conservation Priorities in the Face of Future Development: Applying Development by Design in the Grasslands of Mongolia*. Arlington, Virginia: The Nature Conservancy.

landscape scale, it supports application of mitigation at a more appropriate ecological scale. Projecting cumulative impacts at this scale moves mitigation beyond a piecemeal project-by-project approach to one that can support a dynamic vision for a sustainable landscape.

Step 3: Determine Residual Impacts and Select Optimal Offset Portfolio

Under the DbD framework, proposed development consistent with conservation goals of a landscape-level conservation plan would move forward, using best management practices to minimize impacts and harnessing offsets to mitigate the unavoidable impacts associated with the development. Offsets are increasingly used to achieve environmental benefits (Gibbons and Lindenmayer, 2007), providing a mechanism for maintaining or enhancing environmental values in situations where development is sought despite detrimental environmental impacts (McKenney and Kiesecker, 2010; ten Kate *et al.*, 2004). Offsets address residual environmental impacts of development after efforts have been undertaken to avoid, minimize, and restore them on site, with the overall aim of achieving a net neutral or positive outcome. Offsets offer substantial potential benefits for industry, government, and conservation groups alike. Benefits for industry include a higher likelihood that clearance is granted from regulators for new developments, greater societal support for development projects, and the opportunity to more effectively manage environmental risks. Offsets provide government regulators with the opportunity to encourage companies to make significant contributions to conservation and sustainability goals, particularly in situations where legislation does not require mandatory offsets. Conservation organizations can use offsets to move beyond piecemeal mitigation and thereby secure larger-scale, more effective conservation projects. Offsets can also be a mechanism ensuring that regional conservation goals are integrated into government and business planning.

Our objective with DbD is to ensure that offsets are ecologically equivalent to impacts, are consistent with goals of landscape conservation planning, and will persist at least as long as on-site impacts, resulting in net neutral or positive outcomes. The geographic location of offset sites can be accomplished as a separate stand-alone process (Figure 3) or as part of a landscape conservation plan (Figure 4). Comprehensive mitigation planning is in its infancy, and mitigation will probably occur on a project basis for some time (but see Thorne *et al.*, 2009). Whether conducted as a separate process or incorporated into landscape-level planning, effective offset design must capture impacts to representative biological targets and select offset sites in a manner that captures ecological equivalency and accounts for the landscape value and condition of potential sites (Ball, 2000; Ball and Possingham, 2000; Possingham *et al.*, 2000; Arponen *et al.*, 2007).

Step 4: Estimating Offset Contribution and Progress Toward Goals

Offset policies generally seek no-net-loss or net-gain outcomes for conservation, compensating for impacts with offsets

(McKenney and Kiesecker, 2010). But how do we know when enough offset projects have been implemented to achieve no net loss? Under existing policies, offset benefits are often estimated using mitigation replacement ratios that establish the number of credit units that must be debited from an offset to compensate or replace one unit of loss at the project site. Policy guidance on replacement ratios tends to fall into three categories: predefined ratios, such as those based on the type of conservation action (e.g., 1 : 1 ratio for restoration, 5 : 1 for preservation); specified assessment methods that provide a specific approach for determining ratios; and subjective determinations based on the discretion of regulatory authorities after multiple considerations such as proposed conservation actions and risk factors (McKenney and Kiesecker, 2010). Each approach has weaknesses (Kusler, 2003). Although these approaches may simplify the offset accounting and implementation process, there is little reason to believe they deliver no-net-loss outcomes on a regular basis (King and Price, 2004). In sum, current accounting approaches are generally inadequate for ensuring no-net-loss outcomes. They are either too inflexible to address the ecological context for impacts and offsets, as is the case with predefined ratios and specified assessment methods, or too open to discretion and subjective judgment.

Under DbD, a portfolio of possible offsets is identified that represent the best opportunities for protection or restoration. The portfolio selection process ensures that, in comparison to the impact site, potential offsets provide equivalent or better ecological quality as defined by condition, function, connectivity, and contribution to landscape-level conservation. Such considerations are addressed in the rule-setting process for portfolio selection. After selection of an offset portfolio, the next question is, which offsets in that portfolio should be selected for implementation? The aim is to identify offsets that will deliver the greatest contribution toward achieving no net loss at the lowest cost and risk. Our accounting approach seeks to strike a balance by using ratio determinations based on a more structured and transparent approach. Among several considerations for measuring progress, three important factors to take into account include the following.

1. *Additionality*: an option's new contribution to conservation, which is additional to existing values. Offsets that preserve habitat also deliver conservation value when taking into account real-world conditions and threats; those offsets protect against an expected background rate of loss. For example, protecting a 1000 ha forest area that was experiencing an average deforestation rate of 1% per year delivers a new contribution to conservation of 10 ha per year (1% of 1000 ha).
2. *Probability of success*: the likelihood that an option will deliver expected conservation benefits. Success of restoration projects can vary greatly, depending on the ecosystem, restoration techniques, and other factors. In some cases, restoration approaches are known to be effective, but in other situations there may be great uncertainty due to a lack of experience.
3. *Time lag to conservation maturity*: how long it will take for an offset to deliver conservation value at a level similar to what was lost due to impacts. If an offset takes many years

Species data

+ Landscape rules

= Sites selected

Figure 3 Use of the Marxan algorithm to select suitable offset sites for oil and gas development in the San Juan Basin of Colorado. Spatial data layers were utilized for both assessing impacts as a result of development on the field and selecting suitable offset sites. Landscape rules: Intactness guided the selection of sites to areas of high habitat quality and low oil and gas development potential. Areas hatched represent the best fit of the Marxan algorithm based on these specific targets and specified rules. Inset map shows the location of the development area within the US state of Colorado. For details see [Sochi K and Kiesecker JM \(2011\) Energy by Design: Cooperative Mitigation Planning for the San Juan Basin. Appendix B: Selecting Offset Opportunities](#). San Juan Basin Wildlife Mitigation Plan, Colorado Division of Wildlife, Denver, Colorado.

Composition of potential offset sites

Ecosystem type	Area (km ²)	
Small water bodies	383	0.3%
Dry steppe low elev. flat	87,542	72.9%
Dry steppe low elev. hills	13,212	11.0%
Dry steppe valley bottom	4183	3.5%
Wet salty depressions	14,270	11.9%
Meadow steppe low elev. flat	353	0.3%
Meadow steppe low elev. hills	184	0.2%
Total	120,127	100.0%

Development footprint

Ecosystem type	Area (km ²)	
Small water bodies	810	0.1%
Dry steppe low elev. flat	526,538	74.5%
Dry steppe low elev. hills	83,689	11.8%
Dry steppe valley bottom	27,142	3.8%
Wet salty depressions	68,196	9.7%
Total	706,375	100.0%

Ecosystem type	Area (km ²)	
Small water bodies	2358	0.4%
Dry steppe low elev. flat	306,096	50.2%
Dry steppe low elev. hills	182,521	29.9%
Dry steppe valley bottom	23,795	3.9%
Wet salty depressions	19,267	3.2%
Meadow steppe low elev. flat	6390	1.0%
Mod. dry steppe low elev. flat	34,669	5.7%
Mod. dry steppe low elev. hills	31,464	5.2%
Total	609,907	100.0%

before conservation benefits mature, the time lag represents a loss for biodiversity and should be accounted for in estimates of offset benefits. We propose accounting for this loss by estimating the time to maturity of a restoration action and applying a discount rate, a commonly used method for estimating the present value of future values. With an understanding of the conservation value of different mitigation actions, it is possible to compare these values to the cost of implementing the actions to estimate which actions will provide the highest conservation returns on investment.

We recognize that developing precise estimates for the accounting framework's key factors—additionality, probability of success, and time to conservation maturity—will be challenging in some contexts. But even approximate estimates that have been developed using science-based methods and presented in a transparent process would be a marked improvement over current practices for estimating compensatory mitigation. We firmly believe that offset accounting must incorporate these factors if offsets are to truly deliver on no-net-loss goals.

Applying Development by Design to Achieve Sustainable Landscapes: A Case Study of the WBE

The WBE covers 13.3 million hectares of basin, plain, desert, and 'island' mountains in Colorado, Idaho, Montana, Utah, and Wyoming (Bailey, 1995). US energy demand, energy security issues, and concern over climate change are driving the exploitation of traditional and renewable energy sources abundant in the WBE (McDonald *et al.*, 2009; Copeland *et al.*, 2009). The WBE is home to some of the best onshore wind resources, as well as a significant amount of onshore natural gas deposits (Copeland *et al.*, 2009; Kiesecker *et al.*, 2011b). At the same time, the ecoregion provides critical habitat for migratory big game, songbirds, and raptors within the reaches of the Greater Yellowstone Ecosystem. Some of the world's largest herds of mule deer (*Odocoileus hemionus*) and pronghorn antelope (*Antilocarpa americana*) winter here, relying on the snow-free forage to get them through harsh winter weather. The area is also a stronghold for the greater sage grouse (*Centrocercus urophasianus*), an emblematic native game bird now currently listed as warranted but precluded under the Endangered Species Act. Because of the population declines of several species, including sage grouse, restrictions are increasingly being placed on energy development, curtailing exploitation of both gas and wind resources (Doherty *et al.*, 2010). The current situation appears to be suboptimal for both energy development and conservation. Could we have done better in balancing the competing demands for energy and conservation? In this case study, we apply the DbD framework retrospectively to the WBE to explore how the trajectory of energy development and conservation would have been different over the past four decades. We examine the lessons for

mitigation planning and for promoting sustainable landscapes in the future.

To identify areas that would maintain long-term persistence of representative biodiversity, the Nature Conservancy—along with key state and federal land management and wildlife regulatory agencies, universities, and other conservation organizations—designed an ecoregional plan for the WBE (Freilich *et al.*, 2001). The portfolio of sites chosen during the ecoregional assessment conducted for the WBE (Freilich *et al.*, 2000) totals 3.5 million hectares or 27% of the total area in the ecoregion. Side by side with the WBE's wildlife resources are some of the western US' richest oil and gas deposits (US DOI, 2006; Copeland *et al.*, 2009), including some that intersect areas selected in the ecoregional assessment (Kiesecker *et al.*, 2010). To date, the WBE is home to more than 55,000 oil and gas wells (Figure 5). Conservation of the biological diversity in this ecoregion is in question, in part because the US government has authorized exploration and development in 4 million of the 8 million hectares (52%) of the federal mineral estate within the WBE (Doherty *et al.*, 2008). In fact, the number of producing wells in the ecoregion has nearly tripled from the 1980s to the present and is expected to increase over the next 30 years (Copeland *et al.*, 2007; Doherty *et al.*, 2011; Figure 5). At the same time, declines in populations of several species (i.e., sage grouse) have resulted in restrictions that have impacts on the future of traditional and renewable energy development alike.

Here we use past oil and gas development activities and the portfolio of sites selected in the ecoregional assessment to demonstrate how application of the mitigation hierarchy can be improved to deliver better outcomes for both conservation and development. We located the position of every well drilled in the WBE and made mitigation recommendations for each. Well data were acquired from state-level oil and gas regulatory agencies (Colorado: <http://cogcc.state.co.us/>; Montana: <http://www.bogc.dnrc.mt.gov/onlinedata.asp>; Utah: http://oilgas.ogm.utah.gov/Data_Center/DataCenter.cfm; Wyoming: <http://wogcc.state.wy.us/urecordsMenu.cfmSkip=Y&oops=#oops#>). Where available, we used the spud date (the start of drilling on a new well) to indicate the year a well was put in. In the absence of a spud date, we used other information such as first production date to best approximate the start of activity on a well site. We were unable to establish well activity dates for less than 2% of the original well locations. Records where well status codes (e.g., abandoned location, unapproved permit to drill) suggested no physical activity ever occurred on a proposed well site were not included in the analysis. We focused on wells drilled from 1969 to the present since that is when the National Environmental Policy Act (NEPA) was established. NEPA is an environmental law that established a US national policy promoting the enhancement of the environment and the use of the mitigation hierarchy (Council on Environmental Quality, 2000). We calculated potential disturbance associated with each well and estimated the amount

Figure 4 Use of the ecoregional portfolio to select suitable offsets sites for oil and gas development in the Eastern Steppe of Mongolia. Ecoregional data provides the currency to assess impacts associated with development and compare which portfolio sites are best suited to serve as offset sites. Inset map shows the location of the study area within Mongolia.
